Applications of N-heterocyclic imines in main group chemistry

Tatsumi Ochiai, Daniel Franz and Shigeyoshi Inoue*ab

The imidazolin-2-imino group is an N-heterocyclic imino functionality that derives from the class of compounds known as guanidines. The exocyclic nitrogen atom preferably bonds to electrophiles and its electron-donating character is markedly enhanced by efficient delocalization of cationic charge density into the five-membered imidazoline ring. Thus, this imino group is an excellent choice for thermodynamic stabilization of electron-deficient species. Due to the variety of available imidazoline-based precursors to this ligand, its steric demand can be tailored to meet the requirements for kinetic stabilization of otherwise highly reactive species. Consequently, it does not come as a surprise that the imidazolin-2-iminato ligand has found widespread applications in transition-metal chemistry to furnish pincer complexes or “pogo stick” type compounds. In comparison, the field of main-group metal compounds of this ligand is still in its infancy; however, it has received growing attention in recent years. A considerable number of electron-poor main-group element species have been described today which are stabilized by N-heterocyclic iminato ligands. These include low-valent metal cations and species that are marked by formerly unknown bonding modes. In this article we provide an overview on the present chemistry of main-group element compounds of the imidazolin-2-iminato ligand, as well as selected examples for the related imidazolidin- and benzimidazolin-2-imino system.

Introduction
The imidazolin-2-imino group is a potent electron pair donor

In coordination chemistry nitrogen is particularly recognized for its role as a strong electron-donor atom in ligand systems. Seemingly, this contradicts the fact that this element belongs to the highly electronegative members of the periodic table.

Tatsumi Ochiai was born in Shizuoka, Japan, in 1987. In 2012 he received his MSc degree from the University of Tsukuba under the supervision of Prof. Akira Sekiguchi, for which he received the Dean’s Prize. He worked on heteroatom-substituted tetrahedranes. He then moved to Berlin in 2012 starting doctoral work in the research group of Prof. Shigeyoshi Inoue. His research interest mainly focuses on the synthesis of low-coordinate heavier group 14 elements, metallylenes and metallyliumylidene ions.

Daniel Franz studied chemistry at the Goethe University Frankfurt am Main, Germany, where he received his PhD degree under the supervision of Prof. Matthias Wagner in 2012. Following this he moved to Berlin to carry out postdoctoral studies in the group of Prof. Shigeyoshi Inoue. Today he is pursuing his research interests in coordination chemistry of group 13 and 14 elements at the Technische Universität München under the supervision of Prof. Inoue.
However, the trivalent nitrogen atom in amines, as well as in imines, has high electron density in the form of a lone pair that it readily shares with various types of hard and soft Lewis acids. Tertiary amines and secondary ketimines resemble in their nucleophilic properties but, in sharp contrast, the unsaturated carbon atom of the imino functionality is prone to the reaction with nucleophiles or reducing agents whereas the amino carbon atom is inert (Fig. 1). This reactivity results from the π-interaction with the more electronegative nitrogen atom which provides not only the higher bond order but also drains electron density from the carbon centre in the σ-, as well as the π-scaffold. Due to the orthogonal orientation of the nitrogen lone pair this is not compensated by π back donation. Interestingly, the electronic properties of the imino-nitrogen atom are, vice versa, stronger affected by the characteristics of the carbon atom than it may be the case for the amino-nitrogen centre. In this regard, the electron-rich π-system of an imidazoline ring not only mitigates the electrophilicity of an imino-carbon atom incorporated at the 2-position of the cycle but also pushes electron density to the exocyclic imino-nitrogen atom (Fig. 1). Notably, phosphoramidimines \( (R, P = \text{NR}) \) resemble the imidazolin-2-imines in the electron-donating character of the imino nitrogen atom (Fig. 1). The resemblance of these two ligand classes is reasoned by the similarities in the electronic properties of the parent phosphine and imidazolin-2-ylidene, respectively. Furthermore, one must recognize the isoelectronic relation between imidazolin-2-imines and N-heterocyclic olefins, which function as strong Lewis bases due to the ylide-like nature of the exocyclic alkene bond (Fig. 1).

The allocation of electron density from the five-membered imidazoline ring to the exocyclic nitrogen atom is illustrated by conceivable resonance structures of the anionic imidazolin-2-iminato ligand \( \text{A} \) (Fig. 2). The canonical form \( \text{B} \) in which the exocyclic nitrogen atom bears two formal anionic charges suggests a significant boost of its electron-donating properties as compared to ketimines (Fig. 1 and 2). Form \( \text{C} \) represents the partial N-heterocyclic carbene (NHC) character of the imidazoline moiety (Fig. 2). As apparent from the canonical forms (\( \text{A} - \text{C} \)) the imidazolin-2-iminato ligand represents a σ electron donor with potential to contribute an additional two or even four π-electrons. Consequently, its metal complexes \( \text{A}^M \) may exhibit significant metalla-2-aza-allene \( (\text{B}^M) \) or metalimide \( (\text{C}^M) \) character (Fig. 2). This manifests in an expansion of the imino group’s CN distance and shortening of the N–M bond length. Concomitantly, the C–N–M bond angle is widened to approach the angle of 180° in the ideal CCC allene structure motive. As a result of its electron-donating properties, the imidazolin-2-iminato ligand is an efficient tool for the thermodynamic stabilization of electron-poor species. Moreover, the bulkiness of the imidazoline ring can be conveniently modified to meet individual requirements for kinetic stabilization of otherwise elusive compounds.

The scope of this review

In this article we focus on the coordination chemistry of the imidazolin-2-iminato ligand, as well as the strongly related imidazolidin-2-imino group and the benzimidazolin-2-imino group with regard to main-group elements. For the latter two...
only relevant examples will be given. An earlier review of Kuhn, Frenking and coworkers on imidazolin-2-imines includes main-group metal complexes but dates back about 13 years. The broad spectrum of transition metal complexes that comprise this ligand class and the methods for the synthesis of the ligand have recently been reviewed by Tamm and coworkers and will be discussed only in part. Moreover, only selected examples will be discussed for compounds of this iminato ligand with the non-metals carbon and nitrogen because this belongs to the field of organic chemistry rather than coordination chemistry.

**Group 1 and group 2 element complexes**

**Background**

About 20 years ago Kuhn and coworkers started their pioneering studies on the chemistry of imidazolin-2-imines. A few alkaline and alkaline earth compounds of the imino group were reported but not investigated thoroughly probably because of the pronounced polar nature of the N–M bond (M = alkaline or alkaline earth metal). This puts them in the role of a reactive intermediate for ligand transfer via salt metathesis rather than a species with its own follow-up reactivity with sustainment of the N–M bond. Accordingly, the chemistry of group 1 and group 2 imidazolin-2-iminato complexes is only explored to a minor degree to date.

**Lithium and potassium complexes**

The reaction of LMe2NH (LMe2 = 1,3-dimethyl-imidazolin-2-ylidene) with MeLi in Et2O produces LMe2NLi (1) which is the N-lithiated derivative of the imidazolin-2-imine. The species was characterized by 1H NMR analysis and according to the reported CHN elemental analysis no solvent was present in the isolated material. If the conversion was carried out in THF/Et2O with MeLi that was prepared from H2CCl and elemental lithium synthesis and peroxide from contaminated solvent). Formation of the bulky imino lithium dimer 3 (DiP = 2,6-diisopropylphenyl).

The solid state structure of 2 is marked by a Li12N8O2Cl2 cage that comprises a peroxo moiety in its core (Fig. 3). The authors reasoned that the O22– group resulted from contamination of the solvent with traces of peroxide. Crystals of dimeric [LMe2NLi]2 toluene (3-tolune, LMe2 = 1,3-bis(2,6-diisopropylphenyl)-imidazolin-2-ylidene) were isolated in good yield after the reaction of LMe2NLi with nBuLi in toluene/hexane. Apparently, the formation of higher aggregates is hampered by the bulkier DiP groups (DiP = 2,6-diisopropylphenyl). Bringing into contact LMe2NLi and freshly prepared MeK in Et2O afforded the heavier alkaline derivative LMe2NK (4). The compound was characterized by elemental analysis and its existence was verified by the synthesis of the dithiocarbiminate LMe2NCS2K (5, Scheme 2). Interestingly, the latter shows structural characteristics that account for a bonding situation as represented by resonance structure 5b (Scheme 2) with the C–Nimino bond length significantly increased (a range from 1.369(16) Å to 1.379(18) Å is observed in the solid state structure; cf: 2: C–Nimino = 1.260(4)–1.263(4) Å; 3: C–Nimino = 1.241(3) Å, 1.242(4) Å). Accordingly, the C–S distances in 5a (1.733(13)–1.755(13) Å) resemble typical CS single bond lengths.

**Magnesium complexes**

As rare examples for N-heterocyclic iminato complexes of group 2 metals the magnesium compounds (LMe2NH)MgI2 (61), as well as (LMe2N)2MgI (7) and [(LMe2N)2Mg]2 (8), were reported by Kuhn and coworkers (n ≥ 1). They are accessed through LMe2NH via conversion with 0.25 MgI2, MgMeI and (nBu)2Mg, respectively (Scheme 3). Single crystal XRD (X-ray diffraction) data were obtained for 61 (Fig. 4) while the degree of aggregation (n) of 7 and 8 was not elucidated by structural analysis.

[Scheme 1] Conversion of the imino lithium species 1 into the imino-stabilized LiOCI aggregate 2 (the lithium chloride derives from the methyl-lithium synthesis and peroxide from contaminated solvent). Formation of the bulky imino lithium dimer 3 (DiP = 2,6-diisopropylphenyl).

[Scheme 2] Conversion of potassium imide 4 with carbon disulfide to the thiocarbiminate 5 (represented by resonance structures 5a and 5b).
Group 13 element complexes

Background

Of group 13 elements only a few aluminium complexes with an N-heterocyclic iminato ligand had been reported until respective research was resumed by our group.\(^6\) Reports\(^8\)–\(^10\) in the year 2014 were the first to describe imidazolin-2-imino compounds supported by the high basicity of the ligand. Presumably, the interaction between the lone pair at the imino nitrogen and the unoccupied p-orbital at the boron centre supports the trigonalization of the metalloid atom. Interestingly, this insertion occurs at higher temperatures with more sterically hindered substituents at the boron atom. Moreover, \(\text{H}_2\text{L}^{\text{Mes}}\) \((1,3\text{-dimesityl-imidazolidin-2-yldiene}, \text{NHC saturated at the ligand backbone})\) is subject to ring-expansion reaction at significantly lower temperatures than its congener of very similar sterical encumbrance \(\text{L}^{\text{Mes}}\) \((\text{NHC unsaturated at the ligand backbone})\). It was reasoned that the conjugated ring system in \(\text{L}^{\text{Mes}}\) is more efficient for the delocalization of positive charge density and, thus, stabilizes the boron dihydride form \((\text{LNBH}_2\text{L})\).

Similarly, ring-activation and expansion reaction of \(\text{L}^{\text{Dip}}\) took place by heating the amido-substituted hydridoborane \(\text{L}^{\text{Dip}}\text{BH}_3\text{HNDip}\) reported by Rivard and coworkers.\(^13\)

Conversion of the bis(iminiumtosylate) \(\text{L}^{\text{Mes}}\text{[OTs]}_2\) with \(\text{Li}[\text{BH}_4]\) furnishes the boronium salt \(\text{L}^{\text{Mes}}[\text{OTs}]\) \((\text{Scheme 5})\).\(^\text{10}\) The compound reacts with yellow sulfur to give a rare example of a cationic thioxoborane \(\text{L}^{\text{Dip}}\text{BH}_3[\text{OTs}][\text{S}][\text{S}]=\text{Li}[\text{BH}_4]\) \((\text{Scheme 5})\).\(^\text{10}\) The B–S bond length \((1.710(5) \text{ Å})\) in \(\text{14}^+\) is the shortest that has been reported to date for a molecular complex. Notably, the B–N bond lengths significantly decrease upon transformation of tetrahedral \(\text{13}^+\) into trigonal-planar \(\text{14}^+\) \((\text{13}^+: 1.573(5) \text{ Å}, 1.577(5) \text{ Å}; \text{14}^+: 1.483(5) \text{ Å}, 1.493(5) \text{ Å})\ and, consequently, a partial double bond character can be attributed to the boron–nitrogen interactions in \(\text{14}^+\). Concomitantly, the C–N distances of the imino groups increase \((\text{13}^+: 1.317(5) \text{ Å}, 1.318(4) \text{ Å}; \text{14}^+: 1.359(4) \text{ Å}, 1.363(4) \text{ Å})\) which is in accordance with the formulation of resonance structure \(\text{14}^{\text{AV}}\) \((\text{Scheme 5})\) that represents the delocalization of positive charge density into the N-heterocycles and the polarization of the BS bond towards the sulfur atom \((\text{NBO charge at } S = -0.58; \text{NBO = Natural Bond Orbital})\). DFT (density functional theory) calculations supported the interpretation of the remarkably short B–S distance in terms of a boron sulfur double bond. For example, the HOMO \((\text{highest occupied molecular orbital})\) shows mainly
the sulfur lone pair and the HOMO−1 reveals the B=S π-bonding orbital. The NBO charge at the boron centre of 14° was calculated to be +0.63 which accounts for the boron cation character of the complex as illustrated by the canonical form 14B° (Scheme 5).

Very recently, Rivard and coworkers described the conversion of the imidazolin-2-imino trimethylsilane 15 to the imino boron dichloride 16 and its organyl derivative 17 by the reaction of 15 with BCl3 and PhBCl2, respectively (Scheme 6).14 The bisimino boron monochloride 18 was furnished in a reaction between 15 and 16 (Scheme 6). Moreover, the synthesis of the diphenyl congener 19 was accomplished by conversion of 17 with phenylmagnesium bromide (Scheme 6). The solid state structure of the dihalide 16 hints toward the significant bora-2-aza-allene properties of the CNB moiety (type B3d, Fig. 2) as concluded from the C−N−B bond angle of 180° and the short B−N bond length (1.302(6) Å) which implies high boron−nitrogen double bond character. Remarkably, 16, 17 and 19 react with amine−boranes (RhH3−nNH2BH3; R = H, Me; n = 1, 2) to produce the respective dihydrogenated imino boron compounds LDipNH[B(H)R]n (20−22) with R♭ = Cl for 20; R♭ = Cl, RN♭ = Ph for 21; R♭ = R♭ = Ph for 22) and a mixture of the amine−borane dehydrogenation products (Scheme 6).14 The authors conclude that this imino boron compound acts as an intramolecular frustrated Lewis acid base pair. It should be noted that compound 17 displays catalytic activity in the dehydrocoupling of MenH2BH3 to yield [MenBH3]1 along with oligomeric amine−boranes, which shows its great potential with respect to further application in metal-free catalysis for the dehydrocoupling of amine−boranes and related species.

Aluminium complexes

The bisimino aluminium complexes (LMe2NSiMe3)2AlMe2Cl] (23) and (LMe2-NH)AlMe2Cl] (24) were synthesized by conversion of LMe2NSiMe3 (25) and LMe2-NH, respectively, with 0.5 equiv. of AlMe2Cl]. The ion-separated forms were postulated on the basis of NMR spectroscopic data. The related Lewis acid base adduct LMe2NSiMe3-AlCl3 (26) releases Me3SiCl upon heating the neat compound to 180 °C and is converted into [LMe2AlCl3] (27, Scheme 7).7 An X-ray crystallographic analysis of compound 27 verified its trimeric structure with a six-membered Al3N3 cycle.

The imino aluminium dihydride [LDipNHAlH2]2 (28) results from the reaction of LDipNH with Me3N-AlH3 (Scheme 7).6 From the dihydride one can derive the dihalides [LDipNAlX2]2 (29−31, X = Cl, Br, I) by conversion with BX3 (two equiv.) which were described to form dimers in the solid state, as well as in solution (Scheme 8).7 Obviously, the bulkier iminato ligand in 29 leads to the formation of a four-membered Al4N2 ring with smaller N−Al−N angles (87.8(1)°, 92.3(1)°) in comparison to the six-membered ring in 27 with larger angles (108−110°). Interestingly, the sterically hindered phosphoranimino aluminium dihydride and -dichloride form dimers with four-membered Al3N2 rings
Furthermore, the dihydride 28 reacts with the electrophiles Me₂S/BH₃ (four equiv.) and Me₃SiOTf (two equiv., Tf = triflyl) to yield the aluminum borohydride 32 and the aluminum monohydride triflate 33, respectively (Scheme 8). Notably, the substitution of both aluminum bonded hydrides in 33 for triflate substituents could not be accomplished by the use of a larger excess of Me₃SiOTf, even at elevated temperature. In contrast, the conversion of 28 with only two equiv. of Me₂S/BH₃ does not afford the expected aluminum monohydride borohydride as a product but yields mixtures of 28 and 32. Obviously, the electron withdrawing triflyl groups in 33 mitigate the hydride-donor strength of the remaining AlH functionality. Accordingly, only aluminum monohydride triflates of the related phosphoran-iminato or the 1,3-diketiminato ligand have been reported.¹¹c,¹²a

The conversion of the aluminum dihydride 28 with yellow sulfur affords a rare example of an aluminum hydride hydrogen sulfide complex (34) by insertion of a sulfur atom into the AlH bond (Scheme 8).¹⁶ Similar to 33 the remaining hydride functionalities at the aluminum centres in 34 are less reactive than in the parent compound. However, the transformation with S₈ to form the bis(hydrogen sulfide) 35 can be forced onto the system by heating (90 °C for four days, Scheme 8).¹⁶ As apparent from the XRD study the Al–S distances in 35 (2.231(1)–2.240(1) Å) are slightly shorter than the respective distances in the monohydrogensulfide 34 (2.250(1) Å and 2.252(1) Å).

In order to furnish a heavier aluminum chalcogenide of the imidazolin-2-iminato ligand, 28 was converted with the tellurium atom transfer reagent nBu₃PTe (two equiv.)¹⁷ This conversion yields ditopic aluminium ditelluride 36 as a rare example of an electron-precise aluminium complex with the chalcogen in the oxidation state −1 (Scheme 8). The hydrides left at the aluminium centres in 36 do not react further with excess nBu₃PTe. However, the compound converts with NHC (LEt, 5 equiv., LEt = 1,3-diethyl-4,5-dimethyl-imidazolin-2-ylidene) in a dehydrogenative redox process to form the monotopic aluminium telluride 37 (Fig. 5, Scheme 8) with the chalcogen in the oxidation state −2 along with dihydrogenated NHC (LEt(H₂)).¹⁷

![Scheme 8](image_url)

**Scheme 8** Overview on syntheses of imino aluminium compounds derived from the aluminium dihydride 28: reaction of 28 to the dihalides 29–31, the borohydride 32 and the triflate 33 (X = Cl, Br, I). Synthesis of the aluminium mono- and bis(hydrogensulfides) 34, as well as 35. Conversion of 28 to the ditelluride 36 and its monotopic aluminium telluride offspring 37 (LE₄¹ = 1,3-diethyl-4,5-dimethyl-imidazolin-2-ylidene). Transformation of 37 to ditopic 39 via the presumed intermediate 38.

![Fig. 5](image_url)

**Fig. 5** Ellipsoid plot (30% level) of the aluminium telluride 37 (hydrogen atoms, isopropyl groups and non-N-bonded methyl groups have been omitted).
The structural study of 37 revealed a remarkably short Al–Te distance of 2.5130(14) Å and DFT calculations determined an enhanced aluminium–tellurium–tellurium interaction (WBI_{Al-Te} = 1.20; NPA charges: Al = +1.24, Te = −0.95; WBI = Wiberg bond index, NPA = natural population analysis). It has to be pointed out that the terminal position of the tellurium atom is a very scant structural motif as group 16 atoms commonly assume bridging positions in aluminium chalcogenides. Upon heating a benzene solution of 37 to 80 °C one of the two L_{E2} ligands is released and the putative intermediate L^{DipN}[AlTe]L^{Dip} (38) undergoes aggregation to form 39 (Scheme 8).

The reaction pathway via 38 was suggested by DFT calculations; however, the isolation of a bulkier congener of this elusive species was not accomplished by the use of more sterically hindered NHC. The structural investigation of 39 revealed significantly increased Al–Te distances (2.6143(14), 2.6211(15) Å) and a decreased bond order for the AlTe interaction (WBI_{Al-Te} = 0.75; NPA charges: Al = +1.21, Te = −0.79) with respect to 37.17 It should be noted that in ditopic 39 the aluminium centres are bridged via the tellurium atoms. Notably, 37 and 39 contrast the other given examples for aluminium complexes of the imidazolin-2-iminato ligand in that the aluminium centres are not connected via the nitrogen atoms of the imino groups. Taking into account the marked changes in the Al–Te distances and the values for the WBI_{Al-Te} upon transformation of 37 into 39 the nature of the AlTe interaction in 37 was presumed to possess high Al¼Te double bond character.

**Group 14 element complexes**

**Background**

In initial reports on the chemistry of N-heterocyclic iminato ligands Kuhn and coworkers described the imino trimethylsilane 25 (Scheme 7) which was used as an alternative transmetallation reagent to the alkaline metal salts mentioned above.4,7 Presumably, the bulkier L_{Mes}NSiMe_{3} is formed as an intermediate in the synthesis of L_{Mes}NH via a Staudinger-type reaction described by Cameron, Jenkins, Clyburne and coworkers in 2001.18 Tamm and coworkers established the general method for the preparation of trimethylsilyl-functionalized bulkier imidazolin-2-iminato ligands such as L_{Mes}SiMe_{3} and L^{Dip}NSiMe_{3} in 2004.19 This method has tremendous advantages for the convenient and high-yield synthesis of various imidazolin-2-iminates. Moreover, a silicon atom was incorporated into the spacer group between the imino- and the arene moiety in oligodentate ligands reported by Tamm and coworkers.20 However, it played a rather passive role in the chemistry of the transition metal complexes derived from this ligand system. As outlined in the following section a considerable time elapsed from Kuhn’s initial report until the coordination chemistry of the imidazolin-2-iminato ligand with tetravalent atoms was thoroughly investigated.

**Silicon complexes**

Our group commenced work on main group element complexes of the imidazolin-2-iminato ligand a few years ago and described its complex with a silicon(II) centre in 2012.21 High interest for molecular low-valent silicon compounds originates from their various applications in catalysis and bond activation.22,23 Conversion of L^{DipN}Li with Cp^{*}Si(Br)C_{2}F_{5} (Cp^{*} = pentamethylcyclopentadienyl) as a source of silicon(n) afforded the pentamethylcyclopentadienyl imino silylene 40 with π coordination of the silicon centre by the organyl ligand (Scheme 9). An alternative synthetic route by which 40 can be accessed is via reaction of L^{DipN}Li with Cp^{*}SiBr_{3} followed by reductive dehalogenation of L^{DipN}SiBr_{2}Cp^{*}41. Unfortunately, this method affords only very poor yields of the silylene. DFT calculations on 40 show some π bond interaction between the imino nitrogen lone pair and the unoccupied p-orbital at the silicon centre. The WBI_{SiN} of 0.80 and the Si–N bond length (1.691(5) Å) imply single bond character. Thus, multiple bond interaction as illustrated by the general canonical structures B^{M} and C^{M} (Fig. 2) cannot be concluded for 40. A key motivation of the study was to explore potential silylene–nitrene character of complexes between a low-valent silicon atom and the imidazolin-2-iminato ligand as represented by the canonical structure 40^{A} (Scheme 9). However, structural and theoretical investigation verified the imino-substituted silylene formulation 40 with no relevant silylene–nitrene character (40^{A}). Conversion of 40 with tris(pentafluorophenyl)borane furnished the silylene–borane adduct 42. It is interesting to note that the Cp^{*} ligand is coordinated in a π^{1}-mode with one σ bond to the silicon atom in sharp contrast to the precursor 40, in which π^{1}-mode Si–Cp^{*} bonding is observed. As compared to 40 the Si–N bond length is considerably reduced to 1.605(3) Å and its WBI_{SiN} is increased to 0.90 which account for partial SiN double bond character. The C–N–Si angle of 158.7(3)° in 42 is wider than in 40 (136.6(4)°). Accordingly, the relevant 1-sila-2-aza-allene nature (cf. B^{M}, Fig. 2) can be attributed to 42 as represented by resonance structure 42^{A} (Scheme 9).

In order to exploit the strongly electron-donating properties of an N-heterocyclic iminato ligand for tuning the reactivity of low-valent silicon species Rivard and coworkers attempted the synthesis of a hypothetical bisiminosilylene. Access to the bisiminodibromosilane precursor 43 is granted by conversion of L^{DipN}SiMe_{3} (15) with SiBr_{4} in appropriate stoichiometry (Scheme 10).24 The monoimino derivative L^{DipN}SiBr_{3} (44) is
synthesized in a similar fashion (Scheme 10). The reductive dehalogenation of 43 with KC₈ (excess) yielded the potassium salt 45 instead of the desired silylene (L DipN)₂Si (46, Scheme 10). This product (45) was presumed to result from an intermediate potassium silanide via migration of a Dip group. The formation of minor amounts of the siloxane 47 was reasoned by the presence of silicon grease in the reaction mixture (Scheme 10).

**Germanium complexes**

The reductive dehalogenation of the bulky bisiminodichlorogermaine 48 with sodium naphthalenide affords the bisimino-germylene 49 as reported by Rivard and coworkers (Scheme 11). Notably, the related monoiminotrichlorogermaine 50 was also described (Scheme 11). In the solid state the germanium(i) compound 49 exhibits longer Ge–N distances (both: 1.8194(15) Å) and a decreased N–Ge–N bond angle (99.48(10)°) with respect to its halogenated precursor 48 (Ge–N = 1.7528(14) Å, 1.7582(14) Å; N–Ge–N = 106.33(7)°; Fig. 6). These structural features were interpreted by the authors in terms of a higher p-character of the Ge–N bond in 49 as compared to 48. Theoretical calculations indicated a low singlet–triplet gap of 45.8 kcal mol⁻¹ for the bisimino-germylene 49, a value which is similar to that of the elusive bisiminosilylene 46 (44.5 kcal mol⁻¹). This computational study suggests high inclination for the sterically hindered metal centre to insert into element–element bonds of small substrate molecules. However, upon conversion of 49 with dihydrogen Rivard and coworkers observed the formation of L DipNH as the only soluble species instead of the expected (L DipN)₂GeH₂. This may account for the pronounced proton affinity of the imidazolin-2-imino group. Interestingly, the bisiminogermaine is also not formed in the reaction of 48 with hydride transfer reagents such as K[BH₃Bu₃] or potassium hydride. Another synthetic approach to germanium(ii) complexes of the imidazolin-2-iminato ligand uses the Lappert's germylene ((Me₃Si)₂N)₂Ge as a low-valent metal source. Its conversion with one equiv. of LDipNH at 50 °C furnishes the amino(imino)germylene 51 in the form of a viscous liquid (Scheme 12). The XRD analysis of 52 reveals a Ge–Niminodistance of 1.755(2) Å which is significantly shorter than the Ge–Naminobond length of 1.839(2) Å and also with respect to the free bisimino-germylene 49 (vide supra). Considering the WBIs of the Ge–N bonds in 52 (Ge–Niminino = 0.86, Ge–Naminobond = 0.60) it is reasonable to assume that the bulky imidazolin-2-iminato ligand bonds stronger to the germanium(ii) centre than the bis(trimethylsilyl)-amino group, presumably as a result of the iminato ligand’s higher electron-donating character.

If treated with tris(pentafluorophenyl)borane compound 51 undergoes a methyl-abstraction and ring-closing reaction to form the cyclic germiumylidyldene 53[MeB(C₆F₅)₃] as an example for a cationic complex of germanium(ii) (Scheme 13, Fig. 7). The bonding situation in 53 is found to be suitably described as an amino-bonded cationic germanium(ii) atom that is stabilized via dative bond type interaction with an intramolecularly tethered imino group. This is indicated by a weaker interaction...
between the Ge(n) centre and the N_{imino} atom (Ge–N_{imino} = 1.9694(14) Å, WBI_{GeN} = 0.48) and a stronger bond between the Ge(n) centre and the N_{amino} atom (Ge–N_{amino} = 1.8437(15) Å, WBI_{GeN} = 0.73). This bonding situation between the metal centre and the N atoms appears to be in contrast to the situation in the uncharged congeners 51 and 52 (vide supra). Moreover, the C–N_{imino} distance of 1.335(2) Å in 53\textsuperscript{+} is greater in comparison to 52 (C–N_{imino} = 1.296(3) Å) and hints towards delocalization of cationic charge into the imidazoline ring system similar to the observations reported for 5, as well as 14. This accounts for the pronounced ability of the imidazolin-2-iminato ligand to stabilize cationic species which was verified yet again by a very recent report on the isolation of bifunctional germylene–germyliumylidene.

**Tin complexes**

In 2015 the formation of the amino(imino)stannylene 54 was reported that proceeds in a similar fashion to the lighter congener 51 via reaction of [(Me_3Si)_2N]_2Sn with L\textsuperscript{Dip}NH at 60 °C (Scheme 12).\textsuperscript{26} Notably, the \textsuperscript{119}Sn NMR chemical shift of ~208 ppm for 54 (C_6D_6) is considerably shifted to higher field with respect to the precursor (767 ppm, C_6D_6) which was accredited to an aggregated species in solution with a higher coordinate tin(n) centre. The compound (54) was obtained as a pale red powder and reacted with 4-dimethylamino-pyridine (dmap) to give the solid tin(n) adduct 55 that exhibited a resonance at ~3 ppm in the \textsuperscript{119}Sn NMR spectroscopic analysis (Scheme 12).\textsuperscript{26} The XRD study of 55 shows a shorter Sn–N_{imino} contact (2.058(13) Å) and a longer Sn–N_{amino} distance (2.1647(12) Å). This was interpreted in terms of a stronger bond of the metal centre to the iminato ligand and a weaker interaction with the amino group as described for the germanium congener 52, as well (vide supra).\textsuperscript{25,26} The reaction of 54 with tris(pentafluorophenyl)borane affords the stannyliumylidene salt 56[MeB(C_6F_5)_3] in a methyl abstraction and ring closing reaction similar to the process that afforded the germanium analogue 53[MeB(C_6F_5)_3] (Scheme 13, vide supra). The bonding situations in 56\textsuperscript{+} and 53\textsuperscript{+} resemble, that is, an amino bonded metallyliumylidene cation which is stabilized by a dative bond to the imino group. Accordingly, the Sn–N_{imino} distance of 2.197(2) Å in 56\textsuperscript{+} is longer than the Sn–N_{amino} bond length of 2.062(2) Å which is an observation that is in contrast to that reported for the uncharged congener 55 that possesses a shorter Sn–N_{imino} contact. The isolation of 56[MeB(C_6F_5)_3] is another example for the high potential of N-heterocyclic imino systems to stabilize cationic species. Interestingly, the amino(imino)stannylene 54 converts with azido trimethylsilane to the dimeric tinylidylic acid azide 57 (Scheme 12).\textsuperscript{26} An expected stannamidate of the type L\textsuperscript{Dip}N[Me_3Si][Sn(NSiMe_3)] is not formed but ligand exchange results in the liberation of [Me_3Si][N] from the system. Interestingly, in solution (THF-d_8) dimeric 57 (δ(\textsuperscript{119}Sn) = -285 ppm) exists in equilibrium with a monomeric species (δ(\textsuperscript{119}Sn) = 39 ppm; 57\textsuperscript{`}, Scheme 12).

Very recently, our group described the bisiminochlorostannate 58 which forms by the reaction of L\textsuperscript{Dip}NLi with half an equivalent of SnCl_2,1,4-dioxane (Scheme 14).\textsuperscript{27} The \textsuperscript{119}Sn NMR spectrum of 58 (thf-d_8) shows a resonance at ~18 ppm that is shifted to a lower field in comparison to common monomeric trigonal pyramidal-coordinate 1,3-diketiminato tin(n) chlorides ( ~118 ppm to ~337 ppm).\textsuperscript{28} The XRD analysis of 58 reveals a butterfly-shaped four-membered SnN_2Li stannacycle with no bonding interaction.
between the Sn atom and the Li atom (Fig. 8). The Sn–N imino distances of 2.143(5) Å and 2.179(4) Å are longer compared with that of the dmap adduct 55. The Li–N imino bond lengths of 1.946(9) Å and 2.004(9) Å are comparable to those reported for the imino lithium dimer \[\text{[LDipNLi]}_2\] (toluene) (3/C1 toluene).8

Compound 58 reacts with electrophiles such as I₂, MeI, ClSiMe₃ and MeLi to form oxidative addition products 59–62 (diox = 1,4-dioxane).

![Scheme 14](image)

**Scheme 14** Synthesis of bisiminostannylenoid 58 and reactivity with I₂, MeI, ClSiMe₃ and MeLi to products 59–62 (diox = 1,4-dioxane).

leads to the formation of Me-substituted stannate 62 that exhibited a planar four-membered LiN₂Sn ring in the XRD analysis. Theoretical calculations on 58 revealed the high single-bond character of the Sn–N imino interactions as concluded from the comparison of the WBI values of 58 (0.43 and 0.44) with the ones in 61 (0.24 and 0.24) which mark considerable dative-bond character for the latter. Moreover, the computational study of the natural population analysis (NPA) charge distribution in 58 and 61 shows that the Sn atom in 58 is less positively polarized (+1.22) than that in 61 (+1.42). These theoretical results account for the stannyl anion character of 58 as illustrated by the resonance structure 58A (Scheme 14). However, the amphiphilic reactivity of the tin(n) centre in 58, that is, it functions as a nucleophile in the conversion to 62, has to be pointed out. It allows for the conclusion that the compound (58) possesses high stannylene character and thus represents a heavier congener of carbenoids.

**Miscellaneous: survey of carbon chemistry**

In the field of coordination chemistry the tethering of the exocyclic imino-nitrogen atom of an N-heterocyclic imino group to a carbon atom mostly serves the creation of tailor-made ligand systems. These synthetic methods have been reviewed elsewhere.2,3 They can be complemented by the report of Tamm and coworkers in 2014 on the modified synthesis of the bisimine 1,2-(LiPr₂Me₂N)₂-C₂H₄ (LiPr₂Me₂ = 1,3-diisopropyl-4,5-dimethyl-imidazolin-2-ylidene, Scheme 15), a chelate-fashioned ligand system which had been described before in the year 2007.29,30

**Group 15 element complexes**

**Background**

For the pnictogen family compounds of phosphorus with the imidazolidin-2-imino group (unsaturated in the ligand backbone) to a carbon atom mostly serves the creation of tailor-made ligand systems. These synthetic methods have been reviewed elsewhere.2,3 They can be complemented by the report of Tamm and coworkers in 2014 on the modified synthesis of the bisimine 1,2-(LiPr₂Me₂N)₂-C₂H₄ (LiPr₂Me₂ = 1,3-diisopropyl-4,5-dimethyl-imidazolin-2-ylidene, Scheme 15), a chelate-fashioned ligand system which had been described before in the year 2007.29,30
Most notably, pioneering work on imidazolin-2-imino-substituted phosphines was reported by Kuhn and coworkers in 1996 and 1998. Also, compounds with the imidazolin-2-imino structural motif adjacent to a nitrogen atom are abundant. Examples include common types of organic compounds such as azines of cyclic uraues, cyclic bisguanidines, as well as triazenes and diazotates with the corresponding C5N2 five-membered ring backbone. These will be discussed in the miscellaneous section of this review. Interestingly, the respective chemistry of the heavier pnictogens remains largely unexplored to date.

**Phosphorus compounds**

Phosphorus mononitrides and phosphinonitrenes have developed into an established subgenre of the iminato ligand-stabilized phosphorus chemistry and respective research was sparked by Bertrand and coworkers in 2010. They reported the use of the imidazolidin-2-imino lithium reagent (H2)LDipNLi for the synthesis of the phosphorus dichloride 63 which undergoes reductive dehalogenation with magnesium in the presence of a cyclic alkyl(amino) carbene (CAAC) to afford 64 (Scheme 16, Fig. 9). The authors demonstrated that this compound (64) can be regarded as a molecular congener of phosphorus mononitride stabilized by a CAAC as a ligand to the phosphorus atom and an NHC at the P-bonded nitrogen atom (64A, Scheme 16). This resonance structure (64A) is reminiscent of the diphosphorus compounds 65 and 66 that bear two NHC ligands or two CAACs, respectively (Scheme 16). 33,34

The formulation 64 represents the phosphazabutadiene character of the compound. In the 31P NMR spectroscopic analysis the chemical shift of 64 is observed at 134 ppm which is shifted to a lower field with respect to the heavier congeners 65 and 66 (range: from 59 ppm to −74 ppm). As derived from XRD analysis the geometry of 64 (Fig. 9) was described as trans-bent with a short P−C CAAC bond (1.719(2) Å), as well as an N−C NHC distance (1.282(3) Å) that is in the range of C−N bond lengths of imino groups (vide supra). The P−N distance of 1.7085(16) Å is similar to that of typical P−N single bonds. Oxidation of 64 with Ph3C[B(C6F5)4] (trityl tetrakis(pentafluorophenyl)borate) afforded the radical cation 64+ (Scheme 16).32 This process is reversible as was shown by the regeneration of uncharged 64 via reduction with potassium graphite (KC8, Scheme 16). In the theoretical analysis of 64 and 64+ the shapes of the HOMO and the SOMO (singly occupied molecular orbital), respectively, are very similar. They majorly comprise a π* orbital of the PN group that shows bonding interaction with a p-type orbital at the carbenic atom of the NHC, as well as the CAAC ligand.32 The EPR study of 64+ in frozen fluorobenzene at 100 K revealed g-tensors of gx = 2.0052, gy = 2.0087 and gz = 2.0028 which are comparable to the respective values in 65+ and 66+ 32–34.

The scope of applications of N-heterocyclic imines in phosphorus chemistry was extended in 2011 when Bertrand and coworkers reported the reduction of the bisimino compound 67[OTf] (OTf = triflyl) with KC8 to the uncharged phosphinyl radical 67* (Scheme 17, Fig. 10).35 Notably, the synthesis of 67[OTf] proceeds via the chloride salt 67[Cl] that could not be isolated in analytically pure form at that time but is purified in

**Scheme 16** Synthesis of phosphazabutadiene 64 and its conversion to the radical cation 64+. Phosphorus mononitride formulation 64A, NHC- and CAAC-stabilized diphosphorus complexes 65 and 66.

**Scheme 17** Conversion of the bisiminophosphonium salt 67[OTf] to the phosphinyl radical 67*. Synthesis of the imino(vanadyl)phosphinyl radical 69* via chlorophosphine 68. Vanadium−centre formulation 69A (Np = neopentyl).
the course of the anion exchange (chloride vs. triflate, Scheme 17).\textsuperscript{35} The paramagnetic nature of $^{67}$\textsuperscript{*} was verified by its EPR study at 100 K in frozen THF from which the $g$-tensors $g_x = 2.0074$, $g_y = 2.0062$ and $g_z = 2.0024$ were derived. A comparison with hyperfine coupling constants of atomic phosphorus revealed that an unpaired electron is primarily localized on the $3p(P)$ orbital (62%) with a small contribution of the $3s(P)$ orbital (2%).

Bertrand and coworkers extended their investigation of imino-substituted phosphinyl radicals: the phosphorus dichloride \textsuperscript{63} served as a precursor to the nitridovanadium-functionalized phosphorus monochloride \textsuperscript{68} (Scheme 17).\textsuperscript{35} In an analogous fashion as for $^{67}$\textsuperscript{*} the reduction of \textsuperscript{68} with KC\textsubscript{8} furnished the phosphinyl radical \textsuperscript{69}\textsuperscript{*} (Scheme 17).\textsuperscript{35} From the EPR study of \textsuperscript{69}\textsuperscript{*} $g$-tensors of $g_x = 1.9726$, $g_y = 2.0048$ and $g_z = 1.9583$ were determined. Taking into account the hyperfine coupling constants to $^{51}$V, as well as $^{31}$P it was concluded that the spin density in \textsuperscript{69}\textsuperscript{*} mainly resides on the vanadium centre (67%) and is only localized to a minor degree on the phosphorus atom and the NHC moiety. In contrast, the spin density of the bisimino derivative \textsuperscript{67}\textsuperscript{*} was found to reside with 62% in the $3p(P)$ orbital and with 2% in the $3s(P)$ orbital. In line with the structural and theoretical analysis the authors concluded that the bisimino radical \textsuperscript{67}\textsuperscript{*} is a phosphorus centred radical with little spin delocalization over the iminato ligands. The nitridovanadium congener \textsuperscript{69}\textsuperscript{*}, however, is best represented by the canonical structure \textsuperscript{69}\textsuperscript{**}, that is a vanadium(\textit{v}) complex with a phosphinimide ligand.

In 2012 Bertrand and coworkers reported the remarkable transformation of the azido bisiminophosphonium \textsuperscript{70} to the phosphinonitrene species \textsuperscript{71} \textit{via} irradiation at 254 nm (Scheme 18).\textsuperscript{36} As a starting material the bisiminophosphonium salt \textsuperscript{67}[Cl] was used that had also been implemented in the synthesis of the phosphinyl radical \textsuperscript{67} (Scheme 17).\textsuperscript{35,36} The theoretical analysis of the nitrene (\textsuperscript{71}) suggested that the back donation of a nitrogen lone-pair into accessible $\sigma^*$ orbitals at the phosphorus atom significantly contributes to the thermodynamic stability of the compound. The phosphorus atom in \textsuperscript{71} is the centre of a trigonal-plane and the sum of the angles around the P atom amounts to 360° (Fig. 11). Notably, the P–N\textsubscript{nitrene} bond length of 1.457(8) Å in \textsuperscript{71} is significantly shorter than the P–N\textsubscript{iminio} distances (1.618(8) Å, 1.629(8) Å), as well as the P–N\textsubscript{azido} distance of 1.895(11) Å in the precursor (\textsuperscript{70}). This is in good agreement with the upfield shift in the $^{31}$P NMR spectrum of \textsuperscript{71} (8 ppm) in comparison to \textsuperscript{70} (111 ppm) which indicates the multiple-bond character of the PN functionality. The phosphinonitrene (\textsuperscript{71}) reacts with isopropyl isonitrile (iPrNC) to yield the carbodiimide \textsuperscript{72} that was not structurally characterized (Scheme 18).\textsuperscript{36} In consequence, the created NCNiPr group can be abstracted from the phosphorus atom by implementing isopropyltriflate as an alkylating agent. In the outcome the starting material \textsuperscript{67}\textsuperscript{*} is generated in the form of the triflate salt \textsuperscript{67}[OTf], Scheme 18).

Bertrand and coworkers described the transformation of the phosphinonitrene \textsuperscript{71} to iminophosphonium triflates in 2013.\textsuperscript{37} The methylation or protonation of \textsuperscript{71} using methyltriflate or triflic acid, respectively, furnished \textsuperscript{73}[OTf] or \textsuperscript{74}[OTf] (Scheme 19). The P–N bond length of the phosphoranimine functionality in \textsuperscript{74} amounts to 1.526(2) Å which is longer than the distance of these atoms in the precursor \textsuperscript{71} (\textit{vide supra}, note that the structural parameters of \textsuperscript{73}\textsuperscript{*} are not discussed due to poor data quality).
On the other hand, the $P$–$N_{\text{imino}}$ distances in $74^+$ are decreased to 1.553(2) Å and 1.559(2) Å in comparison to $71$ (vide supra). This suggests a stronger interaction between the $P$-centre and the imino nitrogen atoms and accounts for the potential of $N$-heterocyclic imino systems in stabilizing cationic species. The addition of water to $73$ [OTf] or $74$ [OTf] yielded the cationic phosphine oxides $75$ [OTf] or $76$ [OTf], respectively (Scheme 19). The expected electrophilic properties of $74^+$ were verified by its conversion with dmap that generated the Lewis acid base adduct $77$ [OTf] (Scheme 19). Notably, the $^{31}$P NMR chemical shift of $77^+$ was observed at a significantly higher field ($73$ ppm) compared to the precursor $74^+$ ($73$ ppm).

In 2014 the literature on the phosphinonitrene species ($71$) was enriched by Bertrand and coworkers with their investigation of coinage metal–nitrene compounds. By conversion of $71$ with a corresponding equivalent of copper- or silver triflate (MOTf) the respective complexes with bridging or terminal phosphinonitrene ligands are generated ($78$–$83$, Scheme 20). The reaction of $71$ with two equiv. of MOTf furnished the bimetallic complexes $78$ or $79$ with a bridging nitrenic atom. These showed similar structural features in the solid state, that is, a planar coordination environment of the phosphorus atom and significantly increased $P$–$N_{\text{nitrenic}}$ bond lengths (1.510(5) Å for $78$ and 1.528(3) Å for $79$) with respect to $71$. Furthermore, the $P$–$N_{\text{imino}}$ bond lengths are shortened (1.573(3) Å for $78$ and 1.561(3) Å for $79$) and, vice versa, the $C$–$N_{\text{imino}}$ distances are lengthened (range of 1.31–1.36 Å for $78$ and $79$) which indicates the stronger allocation of electron density from the imidazolidin-2-imino system to the phosphorus atom than in the precursor. After conversion of two equiv. of $71$ with MOTF the linear complexes $82$ and $83$ with terminal bis-(phosphinonitrene) ligands were obtained. Notably, the $M$–$N_{\text{nitrenic}}$ bond lengths (1.801(2) Å, 1.807(3) Å for $82$ and 2.017(3) Å, 2.029(4) Å for $83$) in the linear complexes are decreased in comparison to the bimetallic systems (1.817(3) Å for $78$ and 2.080(3) Å, 2.086(3) Å for $79$). Interestingly, the conversion of the phosphinonitrene and MOTF in a one to one ratio afforded $80$ and $81$, respectively, as confirmed by NMR spectroscopic analysis. However, these compounds were found in a dynamic equilibrium with their bridging and terminal congeners ($78$, $82$ for $80$ and $79$, $83$ for $81$).

A thorough study on the reactivity of the phosphinonitrene $71$ was published in 2015. The authors described its thermal transformation to the iminophosphorane $84$, as well as several conversions with typical small molecule substrates (Scheme 21). At elevated temperature quantitative rearrangement of $71$ was observed. The nitrenic atom inserts into a tertiary carbon CH bond of an isopropyl side chain followed by migration of the Dip moiety to the phosphorus centre to create the five membered PNC3 ring in $84$. The addition of an excess amount of acetonitrile to the phosphinonitrene ($71$) afforded a mixture (16 : 1) of the ketenimine $85$ and the diazaphosphete $86$ (Scheme 21). Notably, the ketenimine is transformed into the diazaphosphete at elevated temperature (90°C). This process was reasoned by the...
initial deprotonation of acetonitrile by the nitrenic centre and nucleophilic attack of the generated cyanoethylidene at the phosphorus atom to afford 85. Subsequent cyclization and proton migration leads to the formation of 86. Reaction of the phosphonitrilic (71) with carbon dioxide or carbon disulfide yields the isocyanate 87 or the isothiocyanate 88, respectively (Scheme 21).39 One should point out the cleavage of the thermodynamically stable C–E double bond (E = O, S) in this process. Compound 71 activates elemental sulfur (S$_8$), as well as white phosphorus (P$_4$).39 The reaction with S$_8$ furnishes the phosphine sulfide 89 that bears a thiosulfynylamino group at the phosphorus atom (Scheme 21). The conversion of 71 with P$_4$ affords phosphorus enriched 90 with a unique P$_2$N moiety via insertion of the PN nitrene fragment into a P–P single bond of the P$_4$ cluster (Scheme 21). With a slight excess of water the phosphinonitrene (Scheme 21) reacted to yield the aminophosphine oxide 91 as the product of the addition of H$_2$O to the PN nitrene bond (Scheme 21).39

By implementing the imidazolin-2-imino trimethylsilane 92 Vidović and coworkers synthesized the imino phosphorus dichloride 93 that was reacted with carbodiphosphorane to yield the phosphonium salt 94[Cl] (Scheme 22).40 The latter was subjected to chloride abstraction with two equiv. of silver hexafluoroantimonate and in the outcome the dicatonic phosphinimine 95[SbF$_6$]$_2$ was formed (Scheme 22).40 The dication assumes a trans-bent structure motif and the P–N distance of 1.594(6) Å is significantly shorter than the respective bond lengths in the CAAC congener (1.645(4) Å). This suggests relevant double bond character for the PN fragment in 95$^{2+}$. As concluded from the theoretical analysis of the dication the authors attributed the increased PN interaction to the removal of electrons from the HOMO which majorly comprises the PN antibonding orbital.

Taking into account structural parameters such as the comparably long C–N$_{imin}$ bond (1.367(8) Å) and bond polarizations derived from the NBO analysis it was presumed that 95$^{2+}$ possesses dicatonic phosphorus mononitrile character to a minor degree (93$^{4+}$, Scheme 22). Regardless of the dominant resonance structure of 95$^{2+}$ its isolation confirms the potential of the imidazolin-2-imino ligand for stabilizing cationic species.

The application of (benz)imidazolin-2-imino substituents as supporting groups for P-based ligands has recently emerged as a subgenre of the field of phosphorus compounds of the iminato ligand. The chemistry relies on the pioneering work of Kuhn and coworkers, who converted L$_{Me2SiMe3}$ (25) to the imino dichlorophosphane 96 (Schemes 7 and 23).310 If treated with AlCl$_3$, this compound reacts to yield the ditopic phosphonium salt 97[AlCl$_4$]$_2$, the structural formulation of which was based on NMR spectroscopic characteristics (Scheme 23).312 The authors described that in solution 97$^{2+}$ is in equilibrium with 96 depending on the nucleophilic properties of the solvent. Moreover, Kuhn and coworkers described the iminophosphanes 98 and 99, as well as the conversion of 99 to the iminophosphorane 100 (Scheme 23).316

In 2015 Mallik, Panda and coworkers reported the imino diphenylphosphine 101 that was converted to the borane adduct 102, as well as the phosphorus chalcogenides 103–106 (Scheme 24).41

Also in 2015 Dielmann and coworkers established the use of imidazolin-2-imino-substituted phosphines as electron-rich ligands to transition metals.42 By lithiation of the benzimidazolin-2-imine BL$_{iPr}$NH (107, BL$_{iPr}$ = 1,3-diisopropylbenzimidazolin-2-ylidene) and reaction with the corresponding chlorophosphines the synthesis of the iminophosphines 108–113 was accomplished (Scheme 25).42 In addition, the conversion of the bulkier L$_{Me2Me2N}$SiMe$_3$ (114, L$_{Me2Me2N}$ = 1,3-dimesityl-4,5-dimethyl-imidazolin-2-ylidene) with the respective chlorophosphines led to the
iminophosphines 115 and 116 in the outcome (Scheme 25). To assess the electron-donor strength of these phosphorus-based ligands the Tolman electronic parameters (TEP) of their nickel tricarbonyl complexes were determined. Moreover, they were evaluated according to the Huynh’s method. The $^{13}$C NMR-spectroscopic shift of the carbene carbon of the BL$iPr$ group is down-field shifted with increasing donor strength of the ligand trans to the BL$iPr$ group. The Huynh’s parameters of the iminophosphines show the same qualitative trend as the TEP analysis. As a result, many of the iminophosphines were found to be more potent electron-pair donors than most electron-rich trialkylphosphines. Remarkably, the authors concluded that the imidazolin-2-imino group instead of acyclic guanidino functionalities was pointed out by the authors. We assume that its implementation rather follows synthetic applicability for furnishing the chiral bis(guanidine)iminophosphorane species. Notably, the scope of catalytic applications of this compound as a chiral uncharged organosuperbase was expanded in recent years.

Miscellaneous: survey of related nitrogen compounds

Compounds in which the exocyclic nitrogen atom of an N-heterocyclic imino fragment bonds to another nitrogen atom are abundant in the literature but may be accounted for in the field of classical organic chemistry rather than inorganic or organometallic coordination chemistry which is the focus of this review. They can be categorized into triazenes (represenative example: 121, Scheme 27), azines (122, subcategory: bisguanidines, Scheme 27), as well as diazotates (123, Scheme 28) and their azoimidazolium (124) derivatives (124[BPh₄], Scheme 28).

Scheme 25 Synthesis of benzimidazolin-2-imino-substituted phosphines 108–113, as well as the imidazolin-2-imino-substituted phosphines 115 and 116. Scheme 27 Synthesis of representative examples for the compound classes: triazenes (121) and azines (122).
Imidazolyl triazenes (121) release dinitrogen under thermal conditions which leads to the formation of imino organyls whereas their exposure to acidic conditions generates a diazonium species along with the imine. The latter accounts for the pronounced proton affinity of the imidazolin-2-imino group. Apart from applications in organic chemistry azines (122) and diazotates (123), as well as their azoimidazolium spin-offs (124[BPh₄]), are found to be employed as ligands to main group elements or transition metals in rare instances. The mechanism for the formation of 124[BPh₄] is proposed to involve AlCl₃-mediated oxygen abstraction to afford the dicationic diazonium compound, followed by its azo coupling with mesitylene. As an interesting difference in their bonding modes the C–Nimino distance in azines is generally shorter than in the reported diazotates. This suggests high CN double bond character along with delocalization of positive charge into the imidazoline ring for the latter. Similarly, the azoimidazolium cation 124⁺ exhibits a comparably long C–Nimino bond length of 1.386(2) Å which indicates that the positive charge is majorly distributed among the atoms of the five-membered ring (Scheme 28, Fig. 12).

**Notes and references**
