# Highly active Co–Al<sub>2</sub>O<sub>3</sub>-based catalysts for CO<sub>2</sub> methanation with very low platinum promotion prepared by double flame spray pyrolysis

Miriam Schubert,<sup>a</sup> Suman Pokhrel,<sup>b</sup> Andreas Thomé,<sup>c</sup> Volkmar Zielasek,<sup>ae</sup>  
Thorsten M. Gesing,<sup>de</sup> Frank Roessner,<sup>c</sup> Lutz Mädler<sup>be</sup> and Marcus Bäumer<sup>\*ae</sup>

Cobalt-based catalysts are often promoted with noble metals to improve the reducibility of the catalyst and provide a high number of metallic Co sites. The high cost of such noble metals requires new synthetic strategies enabling the use of such promoters at as low concentrations as possible. In this article, we present platinum-promoted Co–Al<sub>2</sub>O<sub>3</sub> catalysts with very small concentrations of platinum (between 0.03 and 0.43 wt%) synthesized by double flame spray pyrolysis (DFSP) as a very versatile preparation technique. Catalysts with Pt contents as low as 0.03 wt% Pt lead to a significant improvement in the reducibility of Co<sub>3</sub>O<sub>4</sub> and to high catalytic activity for the CO<sub>2</sub> methanation reaction compared to non-promoted Co–Al<sub>2</sub>O<sub>3</sub>. Upon further increasing the Pt content up to 0.43 wt%, only a slight improvement in catalyst reduction and catalytic activity is observed. All prepared catalysts were characterised using XRD, BET, TPR, TEM and EDX followed by catalytic tests for CO<sub>2</sub> methanation. Furthermore, two different preparation schemes were used for DFSP, where platinum was combusted either with Co or with the Al precursor solution in one flame, which results in catalysts with a tight chemical contact between Pt and Co<sub>3</sub>O<sub>4</sub> or Pt and Al<sub>2</sub>O<sub>3</sub>, respectively. Based on TPR and catalytic tests it could be demonstrated that the deposition of platinum on one or the other oxidic phase has no influence on the reducibility and catalytic performance. The conversion and reducibility were similar for both preparation schemes, an observation which can be explained by H<sub>2</sub> spillover during catalyst reduction and catalytic reaction.

## Introduction

Since CO<sub>2</sub> is a greenhouse gas contributing to global warming, the potential utilization of CO<sub>2</sub> as a carbon source for storing chemical energy would represent an attractive future technology. One approach is the “power-to-gas” concept that includes the catalytic conversion of CO<sub>2</sub> (obtained from lime kilns or coal-fired power plants) and H<sub>2</sub> (generated *via* electrolysis from excess energy using wind or solar plants) to CH<sub>4</sub> for energy storage.<sup>1</sup> The CO<sub>2</sub> methanation process is a well-known catalytic reaction, *e.g.* used in industry for the separation of CO and CO<sub>2</sub> from hydrogen for ammonia synthesis.<sup>2</sup> Different supported catalysts have been investigated for this reaction with Ni or precious metals, with Ru or Rh (ref. 3–11) being the primary focus. While the highest activity is

observed for Ru, it is not of practical interest due to its high cost.<sup>3,12</sup> The use of Ni as a catalyst is much cheaper compared to Ru or Rh but at the expense of a much lower catalytic activity at low temperatures, *i.e.* higher temperatures are needed. In addition, the formation of coke and/or catalyst sintering retards the catalytic rate, eventually deactivating the catalysts at higher temperatures.<sup>13</sup> To overcome this drawback, new thermally stable catalysts with higher activity at lower temperatures are needed.

Bartholomew *et al.*<sup>14</sup> reported the intrinsic activities and selectivities of group VIII metals supported on SiO<sub>2</sub> for CO<sub>2</sub> hydrogenation. They observed a higher turnover frequency (TOF) and selectivity for Co/SiO<sub>2</sub> compared to a nickel catalyst supported on SiO<sub>2</sub>. The high tendency of cobalt catalysts for methane formation is also known from CO<sub>2</sub> Fischer-Tropsch reactions. Yao *et al.*<sup>15</sup> switched the feed gas between CO<sub>2</sub> and CO, demonstrating higher methane yields for CO<sub>2</sub>. The higher methane production was explained by Visconti *et al.*<sup>16</sup> by the lower adsorption rate of CO<sub>2</sub> compared to CO, resulting in a higher H<sub>2</sub>/CO<sub>2</sub> ratio on the catalyst surface. Chakrabarti *et al.*<sup>17</sup> studied CO<sub>2</sub>/CO hydrogenation over CoPt–Al<sub>2</sub>O<sub>3</sub> using <sup>14</sup>CO<sub>2</sub> and proposed two independent reaction pathways for CO and CO<sub>2</sub> conversion so that CO is

mainly converted to higher hydrocarbons, whereas  $\text{CO}_2$  is converted to  $\text{CH}_4$ .

Nevertheless, studies focusing on Co-supported catalysts for the methanation reaction are rare. In the recent literature, the reaction temperature varied between 473 and 673 K, resulting in conversion levels between 30% and 70% and  $\text{CH}_4$  selectivity up to 90%. Zhou *et al.*<sup>18</sup> reported on Co catalysts supported on mesoporous  $\text{SiO}_2$  for  $\text{CO}_2$  methanation leading to moderate  $\text{CO}_2$  conversions of ~50% at 573 K. Similarly, Srisawad *et al.*<sup>19</sup> prepared Co- $\text{Al}_2\text{O}_3$  catalysts with different Co precursors and tested them for  $\text{CO}_2$  methanation at 543 K using unusual  $\text{CO}_2/\text{H}_2$  ratios of 1:10. They claimed that cobalt nitrate is a good precursor for the formation of active catalysts with conversion rates of 75% and  $\text{CH}_4$  selectivity of around 80%. Janlamool *et al.*<sup>20</sup> tested Co-supported MCM-41 and found 30% conversion with a selectivity over 90% at 493 K.

A major problem of Co-supported catalysts is the interaction between the support and the cobalt oxide phase. On the one hand, the support is required to stabilize the Co particles under reaction conditions. On the other hand, the reduction of  $\text{Co}_3\text{O}_4$  to the catalytically active metallic Co is hindered by a too strong metal-support interaction.<sup>21</sup> Another problem is the formation of inactive mixed oxides such as  $\text{CoAl}_2\text{O}_4$ , which affect the catalytic activity.<sup>22,23</sup> To overcome this problem, noble metals such as Ru, Re and Pt have been intensively studied as promoters for supported cobalt FT catalysts facilitating the  $\text{Co}_3\text{O}_4$  reduction.<sup>24,25</sup> In several studies wet chemical preparation techniques, such as incipient wetness or co-impregnation, were employed for the catalyst preparation with platinum contents between 0.1 and 5 wt%.<sup>26–31</sup> An increase in the FT activities with the addition of very small amounts of platinum was observed by Schanke *et al.*<sup>28</sup> using 0.4 wt%, Chu *et al.*<sup>31</sup> using 0.2 wt% and Tsubaki *et al.*<sup>29</sup> using 0.1 wt%. A frequent drawback of wet chemical preparation routes is the difficulty in controlling all structural parameters, such as particle size and size distribution. For example, the crystallite size of  $\text{Co}_3\text{O}_4$  changes by using an  $\text{Al}_2\text{O}_3$  support with different pore sizes.<sup>32</sup> Moreover, in the case of promoted catalysts, the distribution of the promoter on the support material is often not easy to control by standard impregnation techniques. In addition, several preparation steps are necessary for the manufacture of multicomponent catalysts.

In contrast, flame spray pyrolysis (FSP) is a well-established aerosol technique for manufacturing homogeneous nanoparticles in a single step and in large quantities with good control over different structural parameters.<sup>33,34</sup> Here, an organic precursor-solvent combination is dispersed by a gas stream through a nozzle forming a fine spray, which is ignited. In the flame, the precursors evaporate and particles are formed by nucleation.<sup>33</sup> FSP has been used for manufacturing a number of supported catalysts, such as Pt/ $\text{Al}_2\text{O}_3$ , Pt/CeZrO<sub>2</sub>, and different mixed oxides as well as other metal-supported oxides.<sup>35–40</sup> In the case of  $\text{Al}_2\text{O}_3$ -supported Pt catalysts, the deposited particles were found to be well dis-

persed on the alumina surface.<sup>35</sup> A series of  $\text{CoO}_x\text{-Al}_2\text{O}_3$  nanomaterials with  $\text{CoO}_x$  contents ranging from 0% to 100% were prepared by flame spray pyrolysis and characterised by X-ray fluorescence, BET, TEM, XRD, thermogravimetric analysis (TGA) and FTIR.<sup>41</sup> The authors found that this method promotes the formation of a cobalt aluminate spinel phase. In view of catalytic applications, such spinel structures are detrimental.<sup>42,43</sup> In our own earlier studies,<sup>44</sup> we investigated various  $\text{CoO}_x\text{-Al}_2\text{O}_3$  catalysts prepared by single flame (SFSP) and double flame spray pyrolysis (DFSP) and tested them for the Fischer-Tropsch (FT) reaction. The catalysts obtained from the single flame showed no FT catalytic activity due to the formation of Co aluminates. However, by using two nozzles, independent  $\text{Co}_3\text{O}_4$  and  $\text{Al}_2\text{O}_3$  nanoparticle aerosol streams were realized. The intersection of the aerosol streams can be adjusted by changing the angle between the two nozzles. For the given geometry, they intersected at a distance of 0.52 m above the flame, leading to the formation of well-mixed but separated  $\text{Co}_3\text{O}_4$  and  $\text{Al}_2\text{O}_3$  particles. Earlier studies showed that a shorter distance promotes the formation of inactive  $\text{CoAl}_2\text{O}_4$  particles and a larger distance leads to the formation of physically mixed particles with low activity.<sup>44</sup>

In this study, we used the DFSP approach to prepare Pt-promoted  $\text{Co}_3\text{O}_4\text{-Al}_2\text{O}_3$  catalysts. Our aim was to elucidate the effect of the platinum dopant on the reducibility of  $\text{Co}_3\text{O}_4$  and on the catalytic activity for the  $\text{CO}_2$  methanation reaction. To this end, two different precursor combinations were used to obtain particles with either a tight contact between Pt and Co or between Pt and Al. In the first case, the platinum precursor was mixed with the cobalt precursor and combusted in one flame, while the Al precursor was combusted in the second independent flame (tight Co-Pt contact). In the second case, the platinum precursor was mixed with the Al precursor and combusted in one flame, while the cobalt precursor was combusted in the second flame (tight Al-Pt contact). All other parameters were kept the same as reported by Minnermann *et al.*<sup>44</sup> Our results reveal that DFSP can be successfully applied not only for controlled synthesis of  $\text{Co}_3\text{O}_4\text{-Al}_2\text{O}_3$  catalysts, but also to achieve high dispersions of noble metal promoters. The tested low contents of platinum, ranging between 0.03 wt% and 0.43 wt%, make the FSP approach economically interesting as a synthesis technique for highly active  $\text{CO}_2$  methanation catalysts.

## Experimental section

### Nanoparticle preparation

Double flame spray pyrolysis was used for the production of ultrafine powders of non-promoted and Pt-promoted  $\text{Co}_3\text{O}_4\text{-Al}_2\text{O}_3$  catalysts. The required amounts of the metal-organic precursors, such as cobalt naphthenate (Strem Chemical, 5.96% Co in mineral spirits), and aluminium-tri-*sec*-butoxide (97% Sigma Aldrich) were separately dissolved in xylene (VWR, 99.9% pure) to obtain concentrations of 0.50 M and 0.11 M by metal, respectively. For the preparation of Pt-

promoted catalysts, two different precursor–solvent combinations were used, as shown in Fig. 1. For the preparation of catalysts (80 wt% Al<sub>2</sub>O<sub>3</sub> and 20 wt% Co) with Pt in tight contact with Co<sub>3</sub>O<sub>4</sub>, a 50 mL portion of the 0.11 M cobalt naphthenate solution in xylene was mixed with the required amount of Pt acetylacetonate (0.78, 2.58, 5.15 and 13.80 mg for 0.03, 0.08, 0.16 and 0.43 wt% of Pt, respectively) followed by combustion in one flame, while a 50 mL portion of 0.50 M aluminium-tri-*sec*-butoxide was combusted in the second, independent flame (see Fig. 1, scheme A). Similarly, in the second preparation scheme (Fig. 1, scheme B), a 50 mL portion of the 0.11 M cobalt naphthenate solution in xylene was combusted in one flame and a 50 mL portion of 0.50 M aluminium-tri-*sec*-butoxide mixed with the required amount of Pt acetylacetonate (0.78, 2.58, 5.15 and 13.80 mg is 0.03, 0.08, 0.16, 0.43 wt% of Pt, respectively) was combusted in the second, independent flame (see Table 1 for the masses used and the resulting concentrations) leading to a tight Pt–Al<sub>2</sub>O<sub>3</sub> contact.

Catalysts with Pt loadings in the range between 0.03 and 0.43 wt% were synthesized as discussed above, varying the amount of the Pt acetylacetonate. During the DFSP synthesis, the liquid precursors were delivered to the nozzle at a rate of 5 mL min<sup>-1</sup> using a syringe pump and were combusted with O<sub>2</sub> at a flow rate of 5 L min<sup>-1</sup> with a constant pressure drop of 1.5 × 10<sup>5</sup> Pa at the nozzle tip. The distance between the two nozzles and the angle were 0.175 m and 20°, respectively. The sprays were ignited with a premixed mixture of CH<sub>4</sub> and O<sub>2</sub> supplied at rates of 1.5 and 3.2 L min<sup>-1</sup>, respectively. The two aerosol streams met at a distance of 0.52 m above the flame.<sup>44</sup> The ultrafine particles were collected from a filter unit with a diameter of 257 mm placed above the flame reactor at a distance of 0.60 m from the nozzle. One catalyst without Pt promotion and 8 catalysts with Pt amounts between 0.03 and 0.43 wt% (from each preparation scheme) were obtained with this method as summarized in Table 1. The amounts of metallic Co and Pt after catalyst activation (*i.e.* re-

duction of Co<sub>3</sub>O<sub>4</sub> to metallic Co) were calculated and listed in Table 1.

### Brunauer–Emmett–Teller (BET) measurements

BET measurements were carried out using a Quantachrome NOVA 4000e Autosorb gas sorption system. The powders (as prepared) were placed in a test cell and allowed to degas for 2 hours at 473 K under flowing nitrogen. The BET isotherm measurements were performed using nitrogen as an adsorbent at 77 K and relative pressures  $P/P_0$  in the range of 0.01–0.99. From the plot of  $[(P/P_0)/a(1 - P/P_0)]$  versus  $[P/P_0]$  in the range between 0.05 and 0.3, a linear correlation was obtained with the correlation coefficient being greater than 0.999. The BET surface area measurement is related to an average equivalent primary particle size, which was calculated using eqn (1).

$$d_{\text{BET}} = 6/(\rho \cdot S_A) \quad (1)$$

Here  $d_{\text{BET}}$  is the average diameter of a spherical monodisperse particle,  $S_A$  represents the measured surface area of the powder, and  $\rho$  is the theoretical density.<sup>45</sup>

### X-Ray diffraction studies

The freshly prepared catalysts were characterized by X-ray diffraction to identify the phases of the catalysts. The non-promoted Co<sub>3</sub>O<sub>4</sub>–Al<sub>2</sub>O<sub>3</sub> and a selection of Pt-promoted Co<sub>3</sub>O<sub>4</sub>–Al<sub>2</sub>O<sub>3</sub> catalysts were placed in circular sample holders with a diameter of 16 mm which were then loaded into a Bruker D8 diffracting system. The diffractometer was configured in a Bragg–Brentano geometry and equipped with a primary Johansson monochromator producing Cu-K $\alpha_1$  ( $\lambda = 0.1540598$  nm) radiation. A 0.1° fixed divergence, 4° primary, 2.5° secondary Soller slits, and a multi-strip LynxEye detector were used. Continuous scans in the range of 15–100° 2 $\theta$  were applied with an integration step width of 0.0119° 2 $\theta$  and 5.82 s per step. The XRD patterns of the freshly prepared catalysts were refined using DiffraPlus Topas 4.2 software (Bruker AXS, Karlsruhe, Germany) and the structural and microstructural parameters were extracted using Rietveld refinements. Background, scale factor, unit cell parameters and peak width parameters were simultaneously refined in addition to the Lorentzian crystallite size. For the pattern refinement, the structural models for Al<sub>2</sub>O<sub>3</sub> (ICSD: 28260) with space group  $Fd\bar{3}m$ <sup>46</sup> and Co<sub>3</sub>O<sub>4</sub> (ICSD: 28158) with space group  $Fd\bar{3}m$ <sup>47</sup> were employed. The instrumental contribution to the peak broadening was taken into account during the full profile fitting using instrumental parameters derived from a fit of standard crystalline LaB<sub>6</sub>. From the refinement, the wt% Co<sub>3</sub>O<sub>4</sub> and wt% Al<sub>2</sub>O<sub>3</sub> were quantified and compared with the values during synthesis.

### TEM and EDX investigation

TEM images were obtained with a Tecnai F20 S-TWIN microscope equipped with an EDX detector and a GATAN imaging

Fig. 1 DFSP for the preparation of Pt-promoted Co<sub>3</sub>O<sub>4</sub>–Al<sub>2</sub>O<sub>3</sub> catalysts; preparation schema A: Pt in contact with Co<sub>3</sub>O<sub>4</sub> (left); preparation schema B: Pt in contact with Al<sub>2</sub>O<sub>3</sub> (right).

filter. The GATAN imaging filter and the field emission gun were operated at an acceleration voltage of 200 keV for all measurements. Co–Al<sub>2</sub>O<sub>3</sub> catalysts with 0.43 wt% platinum were analysed by TEM before and after catalysis to investigate the influence of the activation and reaction conditions on the nanoparticle phases and shapes. The STEM mode was used to conduct space-resolved EDX and distinguish between cobalt and aluminium nanoparticles.

### Temperature programmed reduction

The reducibility of all catalysts was analysed by inverse temperature reduction (iTPR). The iTPR method indirectly detects the consumption of hydrogen analogous to conventional TPR and is patented by Roessner and Schoenen.<sup>48</sup> The main difference is the shape of the profile. The signal is inverse to standard TPR (H<sub>2</sub> detection with TCD detector), meaning that a decrease in intensity is detected if reduction takes place during the process. For analysis, a powder sample was placed in a quartz tube and exposed to a continuously flowing 5% H<sub>2</sub> gas stream at 50 mL min<sup>-1</sup> while applying a temperature ramp from room temperature to 1273 K. After passing the sample tube, 2 mL min<sup>-1</sup> CO<sub>2</sub> was mixed with the outlet stream and passed through a methanizer at 573 K to produce CH<sub>4</sub>, which in turn was detected by a flame ionization detector (FID). In the absence of reduction, all H<sub>2</sub> reacts with CO<sub>2</sub> resulting in a steady, high FID signal (baseline). The consumption of H<sub>2</sub> during the reduction of the catalysts gives rise to a decreased FID signal resulting in a negative reduction peak.

### Catalytic testing

CO<sub>2</sub> methanation was performed in a U-shaped tube reactor (quartz, internal diameter of 4 mm) with 50 mg of catalysts (sieve fraction of 100–300 μm) diluted with 20 mg of SiO<sub>2</sub> (sieve fraction of 100–300 μm). The catalysts were activated at 673 K under flowing hydrogen for 10 h (heating rate 1 K min<sup>-1</sup>) before starting CO<sub>2</sub> methanation experiments. The reaction was carried out at varying temperatures between 473 and 673 K at 1 × 10<sup>5</sup> Pa and at a CO<sub>2</sub>:H<sub>2</sub> ratio of 1:4 with a

total flow rate of 30 mL min<sup>-1</sup>. The gases were detected for 30 minutes at each temperature to reach steady state conditions. In order to analyse the product gases, a compact gas chromatograph (Global Analyser Solution) equipped with two different columns and two TCD detectors was used. For the parallel detection of the gases two sample loops were loaded in parallel followed by separating them on a Molsieve 5 Å column (15 m, diameter = 0.32 mm) for the detection of Ar (internal standard), H<sub>2</sub>, CO and CH<sub>4</sub> and a Porabond column (15 m, diameter = 0.32 mm) for analysing Ar (internal standard), H<sub>2</sub>, CH<sub>4</sub> and CO<sub>2</sub>. Conversion ( $\bar{X}$ ) and selectivity ( $S$ ) were calculated using eqn (2) and (3), where  $\dot{n}_{\text{CO}_2}$  is the molar flow rate of CO<sub>2</sub> before (in) or after (out) catalytic reaction and  $\dot{n}_{\text{CH}_4}$  and  $\dot{n}_{\text{CO}}$  are the molar flows of CH<sub>4</sub> and CO detected in the product gas stream, respectively.

$$X_{\text{CO}_2} (\%) = \frac{(\dot{n}(\text{in})_{\text{CO}_2} - \dot{n}(\text{out})_{\text{CO}_2})}{\dot{n}(\text{in})_{\text{CO}_2}} \times 100 \quad (2)$$

$$S_{\text{CH}_4} (\%) = \frac{\dot{n}_{\text{CH}_4}}{(\dot{n}_{\text{CH}_4} + \dot{n}_{\text{CO}})} \times 100 \quad (3)$$

## Results and discussion

### Primary particle size ( $d_{\text{BET}}$ ), crystallite size ( $d_{\text{XRD}}$ ) and morphology ( $d_{\text{TEM}}$ )

BET measurements were carried out to determine the specific surface area and to calculate the average equivalent primary particle size ( $d_{\text{BET}}$ ). The latter quantity was derived using a theoretical density obtained from the Rietveld refinements and specific surface areas obtained from BET measurements (Table 3). The specific surface areas varied between 114(5) and 157(5) m<sup>2</sup> g<sup>-1</sup> and the resulting diameters of the spherical particles ( $d_{\text{BET}}$ ) were found to be in the range of 14(1) and 17(1) nm. The freshly prepared Co<sub>3</sub>O<sub>4</sub>–Al<sub>2</sub>O<sub>3</sub> catalysts without platinum doping and a selection of platinum-containing

Co<sub>3</sub>O<sub>4</sub>–Al<sub>2</sub>O<sub>3</sub> catalysts from both preparation schemes were analysed using XRD to quantitatively determine their phases. The results are presented in Fig. 2.

All samples, independent of the preparation scheme or platinum content, show the same diffraction pattern with the highest intensity at 37° 2θ, which confirms the formation of the same phases. To obtain more information about the crystal structure, composition, average crystallite sizes and cell parameters, the diffraction patterns were analysed with the Rietveld method using the structural models for Al<sub>2</sub>O<sub>3</sub> (space group *Fd3m*) and Co<sub>3</sub>O<sub>4</sub> (space group *Fd3m*). Based on these structural models all observed reflections could be described. Representative Rietveld results for Co–Al<sub>2</sub>O<sub>3</sub> + 0.16% Pt are shown in Fig. 3.

**Fig. 2** XRD patterns of the prepared nanoparticles.

The black line shows the measured diffraction pattern while the red line illustrates the intensities calculated using the Rietveld analysis. All diffraction peaks could be indexed as either Co<sub>3</sub>O<sub>4</sub> or Al<sub>2</sub>O<sub>3</sub>, shown in blue and orange, respectively.

The unit cell parameters, theoretical densities and calculated compositions are summarised in Table 2 for all samples. The lattice parameters were found to be 808.2(2) pm for Co<sub>3</sub>O<sub>4</sub> and 790.6(2) pm for Al<sub>2</sub>O<sub>3</sub>. These values agree well with the published lattice parameters of Co<sub>3</sub>O<sub>4</sub> (808.4 pm (ref. 47)) and Al<sub>2</sub>O<sub>3</sub> (790.6 pm (ref. 46)). The calculated composition

**Fig. 3** Rietveld plot of Co–Al<sub>2</sub>O<sub>3</sub> + 0.16% Pt: observed pattern (black), calculated pattern (red), background (grey), refined pattern of Co<sub>3</sub>O<sub>4</sub> phase (blue) and Al<sub>2</sub>O<sub>3</sub> phase (orange), difference between calculated and experimental pattern (black, bottom). Note that a constant background of 12 600 counts was subtracted for better visibility.

was found to be in the range of 21 and 23 wt%  $\text{Co}_3\text{O}_4$ , agreeing well with the amount used during the synthesis (Table 1).

The calculated average crystallite sizes  $L_{\text{Vol}}(\text{IB})$  of  $\text{Co}_3\text{O}_4$  and  $\text{Al}_2\text{O}_3$  are listed in Table 3. Crystallite sizes of  $\text{Co}_3\text{O}_4$  vary between 6.2 and 6.8 nm, whereas the calculated sizes for  $\text{Al}_2\text{O}_3$  are slightly smaller with an average diameter of  $\sim 5$  nm. These crystallite sizes differ from the particle sizes calculated from BET ( $d_{\text{BET}}$ ), which indicates the formation of polycrystalline particles.

Therefore, the samples were further investigated by TEM and EDX. TEM images at two different magnifications of Pt-promoted Co– $\text{Al}_2\text{O}_3$  catalysts with 0.43 wt% Pt were chosen to determine the particle sizes before and after catalysis. For all 4 samples, the diameters of 50 particles were measured to estimate the particle size distribution. EDX was used to distinguish between  $\text{Co}_3\text{O}_4$  and  $\text{Al}_2\text{O}_3$  particles. The investigation was conducted for the catalysts (schemes A and B) with the highest Pt concentration because these two samples showed the highest catalytic performance (see below). The TEM image in Fig. 4(a1) reflects the structure and the particle size distribution of a freshly prepared catalyst according to scheme A and the TEM image in (a2) the structure for the preparation according to scheme B. In both cases, the material consists of spherical particles in the range of 5 to 20 nm. Mainly two fractions of particles occur: one fraction of particles with an average size between 6 and 8 nm and a second fraction with diameters between 12 and 14 nm. Only a small amount of the particles was larger than 15 nm. Comparing the particle sizes before and after catalysis clearly demonstrates that no sintering took place under reaction conditions after 210 minutes time on stream, indicating a good thermal stability. Due to the fact that the crystallite sizes of  $\text{Al}_2\text{O}_3$  and  $\text{Co}_3\text{O}_4$  calculated from XRD were found to be in the range of 5 to 6.5 nm, it can be assumed that the smaller particles are

fully crystalline and larger particles consist of polycrystalline particles. Platinum particles could not be detected, suggesting a very fine dispersion with small particles or clusters of a few platinum atoms.

To shed light on the question which of the particles observed by TEM are  $\text{Co}_3\text{O}_4$  and which are  $\text{Al}_2\text{O}_3$ , single particles were analysed using EDX in STEM mode. Fig. 5 shows TEM images and the corresponding STEM images including the areas used for an EDX analysis. For 6 single particles, the Co/Al/O ratios were calculated from the EDX measurements and are listed in Table 4. The values in brackets describe the error of the EDX software for quantitative analysis. All the analysed particles contain oxygen in the range of 56% to 70%. The large particles (no. 5 and 6;  $\sim 15$  nm) consist only of oxygen and aluminium, identifying them as  $\text{Al}_2\text{O}_3$  particles. Taking the XRD results into account, the data imply that the  $\text{Al}_2\text{O}_3$  particles are polycrystalline and consist of smaller  $\text{Al}_2\text{O}_3$  crystallites. For the smaller particles (no. 1, 3 and 4) both cobalt and aluminium could be detected by EDX. Yet, based on the fact that the concentration of Al is much lower as compared to Co, the smaller particles are most probably crystalline  $\text{Co}_3\text{O}_4$  particles. The Al signal probably results from the surrounding  $\text{Al}_2\text{O}_3$  particles.

Platinum could not be detected by EDX so that it was not possible to prove that Pt is in direct contact with either  $\text{Co}_3\text{O}_4$  or  $\text{Al}_2\text{O}_3$  depending on the preparation scheme. Apparently, the synthesis results in a very fine dispersion of low Pt content. However, it is known from earlier studies of a Pt– $\text{TiO}_2$  system prepared by single flame spray pyrolysis (SFSP) that Pt particles are completely formed and deposited on the oxide support already after 0.12 m in the flame.<sup>49</sup> Even though for this study a different support material was used, the particle streams meet after approx. 0.52 m so that it can be safely assumed that Pt is deposited on the oxide of the

Fig. 4 TEM images of Pt-promoted  $\text{Co}_3\text{O}_4$ – $\text{Al}_2\text{O}_3$  catalysts before activation (a1 and a2) and after catalytic testing (b1 and b2) from both preparation schemes and the corresponding particle size distribution calculated from TEM.

precursor (Co or Al) with which it was combusted in one flame.

### Temperature programmed reduction

The reducibility was detected to study and compare the reducibility of  $\text{Co}_3\text{O}_4$  for all catalysts. The reduction of  $\text{Co}_3\text{O}_4$  takes place *via* two distinct steps. In the first step,  $\text{Co}_3\text{O}_4$  is reduced to CoO and in the second step to metallic Co. The TPR profiles of supported cobalt catalysts are more complex due to interactions between  $\text{Co}_3\text{O}_4$  particles and the oxidic support compared to unsupported  $\text{Co}_3\text{O}_4$ . Thus, oxide-support interactions inhibit the reduction of  $\text{Co}_3\text{O}_4$  leading to shifts of the reduction signals to higher temperatures.<sup>50–52</sup> With the addition of noble metals such effects can be reduced due to increased availability of hydrogen on the surface.<sup>53</sup> Fig. 6 shows the TPR profiles for the non-promoted  $\text{Co}_3\text{O}_4\text{-Al}_2\text{O}_3$  (bottom) and platinum-promoted catalyst (with increasing platinum content from top to bottom) from preparation scheme A, where platinum was sprayed together with cobalt in one flame, hypothesizing that there might be a tighter contact between Pt and Co as compared to that in preparation scheme B.

The TPR profile for the non-promoted catalyst (Fig. 7:  $\text{Co-Al}_2\text{O}_3$ ) shows three main signals. The first peak occurring at  $\sim 600$  K suggests the reduction of  $\text{Co}_3\text{O}_4$  to CoO and the

broad peak between 720 and 1000 K the subsequent reduction of CoO to metallic Co. A third shoulder at  $\sim 1150$  K is attributed to the reduction of  $\text{CoAl}_2\text{O}_4$ .<sup>54,55</sup> The high intensity of the signal between 720 and 1000 K is an indication of strong interactions between the  $\text{Al}_2\text{O}_3$  and the CoO nanoparticles.<sup>56</sup> In general, strong metal-support interactions are characteristic of  $\text{Al}_2\text{O}_3$ -supported Co catalysts.<sup>53</sup> On the one hand, such interactions lead to high sintering stability, *i.e.* very stable Co particles on the support. On the other hand, the reduction of the catalysts is more difficult compared to catalysts with weaker metal-support interaction.

Unlike non-promoted  $\text{Co-Al}_2\text{O}_3$ , the platinum-promoted catalysts show significant TPR shifts to lower temperatures. For a better illustration, the two main reduction steps in the series of different Pt amounts are connected with a red line. The maximum of the high temperature reduction peak, representing the reduction to metallic cobalt, shifts by

Fig. 6 TPR profiles for  $\text{Co-Al}_2\text{O}_3$  catalyst without and with 0.03–0.43% platinum prepared according to preparation scheme A with platinum and cobalt in tight contact.

Table 4 Composition of single particles calculated from EDX analysis

EDX no.	Co/wt%	Al/wt%	O/wt%
1	34(5)	10(2)	56(5)
2	4(1)	29(2)	67(3)
3	21(4)	9(2)	70(5)
4	25(5)	11(2)	64(5)
5	0(0)	40(3)	60(2)
6	0(0)	33(2)	67(3)

Fig. 7 TPR profiles for Co–Al<sub>2</sub>O<sub>3</sub> nanoparticles without and with 0.03–0.43% platinum prepared according to preparation scheme B with platinum and aluminium in tight contact.

around 300 K (compared to unpromoted Co–Al<sub>2</sub>O<sub>3</sub>) to lower temperatures and reaches a new maximum between 695 and 665 K for the highest platinum loading. The low-temperature reduction peak, which represents the first reduction step to CoO, is also shifted to lower temperatures for the samples with 0.03 and 0.08 wt% Pt to 525 K. However, there is still a small shoulder at ~575 K (see arrow) in the same range where the first peak was also detected for the non-promoted catalysts, but with increasing platinum content the shoulder at 575 K disappears and the maximum of the low-temperature peak further shifts to 495 K. Thus, the beneficial effect of platinum is clearly demonstrated by TPR. An enhanced reducibility of platinum-containing samples is well known for supported Co<sub>3</sub>O<sub>4</sub> catalysts and is attributed to the high affinity of platinum for H<sub>2</sub> activation and a subsequent hydrogen spillover to Co<sub>3</sub>O<sub>4</sub>.<sup>25,57</sup> Due to the high availability of hydrogen on the surface, the reduction of Co<sub>3</sub>O<sub>4</sub> is enhanced.

Yet, the distinct effect of even very low Pt contents (0.03 wt%) is striking. Usually, Co-catalysts are promoted with platinum contents in the range of 0.5 to 1 wt%. The lowest contents of 0.1 and 0.2 wt% Pt for catalysts prepared by incipient wetness impregnation were reported by Chu *et al.*<sup>31</sup> and Tsubaki *et al.*<sup>29</sup> Such low concentrations reported here for the first time might be economically viable for the industrial large-scale production of such novel catalysts. It can be supposed that the DFSP technique is decisive for the good performance at such low platinum contents. As a result of the atomization in the aerosol stream, Pt can be finely distributed on the Co<sub>3</sub>O<sub>4</sub> or Al<sub>2</sub>O<sub>3</sub> particles, respectively, so that later on – during reduction and reaction – a good accessibility for hydrogen is ensured.<sup>49</sup>

The TPR data from the catalysts prepared according to scheme B (Pt in tight chemical contact with Al<sub>2</sub>O<sub>3</sub>) are depicted in Fig. 7. It can be assumed that the tight contact between the promoter and Co is very important for enhanced catalytic reduction as demonstrated by Nabaho *et al.*<sup>58</sup> These authors prepared three different catalysts by incipient wet-

ness impregnation: (1) a non-promoted Co–Al<sub>2</sub>O<sub>3</sub> catalyst, (2) a chemically (by impregnation) promoted CoPt (0.5 wt%)–Al<sub>2</sub>O<sub>3</sub> catalyst and (3) a 0.5 wt% Pt–Al<sub>2</sub>O<sub>3</sub> catalyst. The non-promoted and chemically promoted CoPt–Al<sub>2</sub>O<sub>3</sub> catalyst and a physical mixture of Pt–Al<sub>2</sub>O<sub>3</sub> and Co–Al<sub>2</sub>O<sub>3</sub> were characterized by TPR. In the first experimental observation, the physically mixed catalyst showed the same TPR profile as a Co–Al<sub>2</sub>O<sub>3</sub> catalyst without platinum. However, after milling the physical mixture of Co–Al<sub>2</sub>O<sub>3</sub> and Pt–Al<sub>2</sub>O<sub>3</sub>, the TPR profile shifted to lower temperatures, showing improved reduction as compared to the chemically prepared CoPt–Al<sub>2</sub>O<sub>3</sub> catalyst. From this observation it can be concluded that the direct interaction between cobalt and platinum is not the driving force for Co<sub>3</sub>O<sub>4</sub> reduction, rather a short distance between Pt and Co enables H<sub>2</sub> spillover from Pt to Co<sub>3</sub>O<sub>4</sub>. Comparing the TPR profiles of the catalysts prepared according to schemes A and B in the present investigation (Fig. 6 and 7), almost the same shifts towards lower temperatures are observed. The peak maxima (also connected with a red line) representing the reduction of CoO to metallic cobalt are detected between 530 and 470 K depending on the platinum content.

The results also show small reduction peaks in the temperature range between 500 and 575 K for the catalysts with 0.03 and 0.08 wt% Pt, respectively. Further increasing the platinum content, however, leads to new peak maxima at a temperature lower than 470 K. In summary, very similar TPR data from platinum-promoted catalysts prepared according to schemes A and B are obtained. This similar reduction behaviour can be explained by hydrogen spillover from Pt (on top of Al<sub>2</sub>O<sub>3</sub>) to Co<sub>3</sub>O<sub>4</sub> during the reduction process. The activation and spillover of hydrogen is schematically depicted in Fig. 8 for both structural situations. In the first case, Pt is in tight contact with Co<sub>3</sub>O<sub>4</sub> and hydrogen can directly react with Co<sub>3</sub>O<sub>4</sub> to form Co and H<sub>2</sub>O. In the second case, where Pt is in tight contact with Al<sub>2</sub>O<sub>3</sub>, the activated hydrogen can diffuse on the Al<sub>2</sub>O<sub>3</sub> surface *via* spillover to Co<sub>3</sub>O<sub>4</sub>. Baeza *et al.* studied the extent of hydrogen spillover on different supports. The extent decreased in the following order:  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> > C >

Fig. 8 Schematic drawing illustrating the activation and spillover effect occurring on DFSP catalysts with tight contact between Pt and Co or Pt and Al.

$\text{SiO}_2 > \text{MgSiO}_3$ . This was explained by the level of surface acidity or the presence of OH groups.<sup>59</sup> As reported by Nabaho *et al.*,<sup>58</sup> a short distance between Pt and Co is necessary to enable the  $\text{H}_2$  spillover from Pt to  $\text{Co}_3\text{O}_4$ . A few researchers also reported very large distances for spillover hydrogen on a physical mixed material or on packed beds. For example, Roland *et al.*<sup>60</sup> reported H spillover of over several millimetres on a Pt-zeolite/H-zeolite system at room temperature. Lenz *et al.*<sup>61</sup> studied the spillover distance from  $\text{PtAl}_2\text{O}_3$  to  $\text{SiO}_2$  by NMR and found that H diffused by 12 cm to reach the probe area of the NMR system. The conclusion of the authors was that hydrogen interacts with the surface OH groups as a radical. Nevertheless, in our case the  $\text{Co}_3\text{O}_4$  and  $\text{Al}_2\text{O}_3$  particles prepared by DFSP are well mixed, meaning that each  $\text{Co}_3\text{O}_4$  particle is surrounded by several  $\text{Al}_2\text{O}_3$  particles. Thus, it can be estimated that the maximal diffusion distance is approx. 10 nm (equal to the  $\text{Al}_2\text{O}_3$  particle size). Furthermore, reported hydrogen diffusion coefficients on oxides such as Pt/ $\text{SiO}_2$  or  $\text{Al}_2\text{O}_3$  are in the range of  $10^{-6} \text{ cm}^2 \text{ s}^{-1}$  at 473 K.<sup>62</sup> Taking the Einstein relation with  $x^2 = 4Dt$  into account, where  $D$  is the diffusion coefficient,  $t$  is the diffusion time and 4 is the coefficient for two-dimensional diffusion, a diffusion distance of around 20 000 nm  $\text{s}^{-1}$  would be possible at a low surface coverage. We cannot completely exclude that Pt migration from  $\text{Al}_2\text{O}_3$  to  $\text{Co}_3\text{O}_4$  takes place during catalyst activation, but, due to the fact that hydrogen spillover is very fast, the availability of hydrogen is not likely to be limiting for the reduction of  $\text{Co}_3\text{O}_4$  independent of the preparation scheme, *i.e.* even if Pt is located on  $\text{Al}_2\text{O}_3$ .

### Catalytic tests for $\text{CO}_2$ methanation reaction

All non-promoted and promoted catalysts were tested for  $\text{CO}_2$  methanation at different temperatures after activating the catalyst at 673 K under  $\text{H}_2$  flow for 10 h. The  $\text{CO}_2$  conversion and  $\text{CH}_4$  selectivity at different temperatures for catalysts prepared according to schemes A and B are plotted in Fig. 9 and 10, respectively. For all catalysts – non-promoted and promoted catalysts independent of the preparation scheme – the conversion of  $\text{CO}_2$  increases with increasing

temperature. For the non-promoted catalyst, the  $\text{CO}_2$  conversion rises from 25% at 573 K to ~60% at 673 K. Already very low Pt contents (0.03 wt% Pt) double the conversion at low temperatures (573 K: ~55%) and the highest achievable conversion in the studied temperature range increased to ~70% at 673 K. Upon further increase of the platinum content only slight increases of the  $\text{CO}_2$  conversion can be observed (5% to 10%). Notably, the  $\text{CO}_2$  conversion is almost identical for the catalysts prepared according to scheme A or B.

The conversion rate is directly related to the amount of available metallic Co sites and the supply of dissociated hydrogen on the surface.<sup>63,64</sup> It can be assumed that a higher amount of active Co sites can be formed during activation in the presence of platinum due to a more effective reduction, as revealed by our TPR profiles, where the reducibility was significantly improved for the promoted catalysts independent of the preparation scheme. In addition, more activated hydrogen is available on the surface during catalysis in the presence of platinum, which may also increase the conversion rates. As discussed above, H spillover is fast, explaining why the conversion rates between catalysts prepared by scheme A and B are comparable, independent of whether Pt is deposited on  $\text{Al}_2\text{O}_3$  or  $\text{Co}_3\text{O}_4$ .

The two products obtained during the reaction were CO and  $\text{CH}_4$  for all samples. The  $\text{CH}_4$  selectivity is found to increase with increasing  $\text{CO}_2$  conversion for all catalytically analysed samples (see Fig. 10). The platinum-promoted catalysts show comparable selectivities of between 80% and 98%, whereas the non-promoted sample reaches only 72–88%  $\text{CH}_4$  selectivity.

Two different mechanisms are discussed for the  $\text{CO}_2$  methanation reaction in the literature. Lahtinen *et al.*<sup>64</sup> reported a one-step mechanism, where  $\text{CO}_2$  is dissociated into carbon and oxygen on the catalyst surface. Carbon can then be directly converted with dissociated hydrogen to methane. The rate-limiting step was found to be the removal of surface oxygen. The second mechanism reported is a two-step reaction, where  $\text{CO}_2$  is first converted to CO in a reverse water gas shift reaction. CO is then converted to  $\text{CH}_4$ .<sup>65</sup> Due to the fact that cobalt is not reverse-water-gas-shift active and

Fig. 9 Temperature-dependent  $\text{CO}_2$  conversion for the non-promoted  $\text{Co-Al}_2\text{O}_3$  nanoparticles and platinum-promoted nanoparticles prepared according to preparation scheme A (tight contact of Pt and Co) and B (tight contact of Pt and Al).

Fig. 10  $\text{CH}_4$  selectivities at different  $\text{CO}_2$  conversions for the non-promoted  $\text{Co-Al}_2\text{O}_3$  catalyst and for the platinum-promoted catalysts prepared according to preparation scheme A (tight contact of Pt and Co) and scheme B (tight contact of Pt and Al).

the RWGS does not take place at temperatures below 400 °C, the one-step mechanism is most likely.<sup>66,67</sup> Furthermore, if CO would be an intermediate of  $\text{CH}_4$ , the main product would be CO at low conversion levels. Since  $\text{CH}_4$  selectivity is approx. 80% at 5%  $\text{CO}_2$  conversion, it can be assumed that both CO and  $\text{CH}_4$  are primary products. One possible reaction mechanism is the dissociation of  $\text{CO}_2$  on the cobalt surface to surface carbon and CO. Surface carbon is then hydrogenated to  $\text{CH}_4$  and CO can desorb (see Fig. 11).

Nevertheless, from our results it can be concluded that activated hydrogen has an enhancing effect on the selectivity. A higher amount of hydrogen on the surface may increase the rate of methane formation and the removal of surface oxygen by water formation at the same time. The consequences are higher amounts of  $\text{CH}_4$  formed, less CO and a higher regeneration rate of Co sites during catalysis.

All catalysts independent of the preparation scheme show a similar behaviour during activation, as demonstrated with TPR, and under catalytic reaction conditions. The exceptional conversion rate for very low Pt quantities (0.03 wt%) and the precise control of catalyst composition, phase and morphology, which was demonstrated by XRD, TPR and catalytic tests, is worth noting. Overall, the results demonstrate that DFSP is a promising preparation technique for precisely adjusted catalysts.

Fig. 11 Schematic description of the spillover effect during  $\text{CO}_2$  methanation on platinum-promoted DFSP catalysts.

## 4. Conclusion

In this article, we have presented the properties and catalytic activity of non-promoted and Pt-promoted  $\text{Co}_3\text{O}_4\text{-Al}_2\text{O}_3$  catalysts prepared by DFSP. In particular, the impact of platinum in the range between 0.03 and 0.43 wt% was studied. For the preparation of catalysts with a tight contact between Pt and Co, platinum and cobalt precursors were mixed and combusted in one flame, while an Al precursor solution was simultaneously combusted in the second flame (scheme A). In the second approach, a solution of platinum and aluminium were mixed and combusted, while the Co precursor solution was combusted in a second flame (scheme B).

Our key findings from TPR and catalytic tests are that only 0.03 wt% Pt can significantly increase the reducibility of the catalysts and the methanation rate compared to the non-promoted catalysts independent of the preparation scheme, *i.e.* deposition of Pt on  $\text{Co}_3\text{O}_4$  or  $\text{Al}_2\text{O}_3$ . The performance of all promoted samples with 0.03 to 0.43 wt% followed the same trend, *i.e.* increase in reducibility,  $\text{CO}_2$  conversion and  $\text{CH}_4$  selectivity upon Pt deposition. Hence, the homogenous distribution of Pt between  $\text{Al}_2\text{O}_3$  and  $\text{Co}_3\text{O}_4$  particles enables hydrogen spillover from platinum to cobalt and/or Al.

In summary, our results clearly demonstrate the great potential of the double flame spray pyrolysis as a method for catalyst manufacturing.
