Direct delamination of graphite ore into defect-free graphene using a biphasic solvent system under pressurized ultrasound†

H. Beneš,^a R. K. Donato,^b P. Ecorchard,^{*c} D. Popelková,^{ac} E. Pavlová,^a D. Schelonka,^c O. Pop-Georgievski,^a H. S. Schrekker^{*b} and V. Štengl^c

The study reported herein describes for the first time a method for producing defect-free graphene directly from its mineral ore. This was achieved by treating graphite ore in an ionic liquid containing biphasic solvent system, applying pressurized intense cavitation ultrasound. Without any graphite ore pre-treatment, large few layer thick graphene sheets, as well as micrometric layered crumpled graphene structures, were produced. This opens new opportunities for the development of graphene-based technologies.

Introduction

Since the 1940s, graphene sheets of interconnected sp²-hybridized carbon atoms have been known.¹ Although this material was considered as “unrealistic” due to its synthetic hurdles and low thermodynamic stability at ambient conditions, Geim and Novoselov changed this perspective in 2004.^{2–4} From this point of showing that graphene is a “possible” material with a huge potential for the development of high-tech applications, intensive research efforts have been focused on enhancing its accessibility.

Nowadays, few-layers thick graphene nanosheets can be produced by several methods; such as mechanical exfoliation (repeated peeling),⁴ solvation force-induced exfoliation,⁵ and chemical oxidation/reduction^{6–8} of graphite, unrolling of multiwall carbon nanotubes (MWCNT),^{9–11} epitaxial growth,¹² chemical vapor deposition (CVD),¹³ electrochemical reaction¹⁴ and gas-phase synthesis.¹⁵ Common drawbacks of these techniques are very low yields, high-energy demands and/or necessity to use expensive high-quality substrates. Another important aspect to consider is the quality of the produced graphenes. For instance, the chemical reduction of oxidized graphite is incomplete and produces graphenes with residual functional groups, causing the loss of the inherent graphene properties (*i.e.* electrical, mechanical and thermal properties).^{16,17}

Therefore, the choice of the proper chemicals and processing conditions is essential for obtaining defect-free graphene nanosheets.

Within this context, sonication of graphite has shown to be a powerful tool for the preparation of graphene, although this requires the adjustment of the medium's surface energy close to that of graphene ($\sim 68 \text{ mJ m}^{-2}$).^{26,27} Besides the medium's surface energy, the strength of the medium-graphene physical interaction is another important parameter. A variety of solvents and solvent combinations that prevent reverse graphene aggregation (*e.g.* ethylene glycol, dimethylsulfoxide [DMSO], dimethylformamide [DMF], *N*-methyl-pyrrolidone [NMP], *c*-butyrolactone, dimethylacetamide, or its mixtures with water) have been successfully applied in the exfoliation of graphite under high-intensity ultrasound waves from an ultrasound horn, producing solvated graphene flakes.^{18,19} This strategy allows the preparation of graphene monolayer dispersions in DMF,^{20,21} benzene²² and NMP.^{19,23} In addition, the medium's surface energy can be adjusted by the addition of a surfactant, which has been achieved with sodium dodecylbenzene sulphonate in a water solution, providing stable graphene suspensions.²⁴ Despite these advances, the maximum achieved graphene sheets concentrations remain low, around 1 mg mL^{-1} .²⁵

Considering the potential use of surfactants and the importance of the physical medium-graphene interaction, imidazolium ionic liquids (IL) open new opportunities. The π -electron cloud of the imidazolium cation provides relatively strong interactions with various π -electronic carbon nanomaterials, including MWCNT, fullerenes and graphene.²⁸ Besides the successful application of imidazolium IL in the unrolling and dispersion of MWCNT,¹⁰ a few studies have been reported about its use as a medium in the direct exfoliation of graphite into graphene sheets. Wang *et al.* employed ultrasound to directly exfoliate graphite flakes in the IL 1-*n*-butyl-3-methylimidazolium

bis(trifluoromethanesulfonyl)imide (BMImNTf₂), which was followed by high-speed centrifugation to remove the fast sedimenting non-exfoliated graphite.²⁹ The supernatant IL suspension contained up to 0.95 mg mL⁻¹ of graphene sheets. Nuvoli *et al.* showed that a more concentrated graphene-IL suspension (5.33 mg mL⁻¹) could be obtained when grinding graphite flakes and 1-*n*-hexyl-3-methylimidazolium hexafluorophosphate in a mortar, before sonication.³⁰ The produced graphene sheets exhibited an average thickness of ~2 nm (6–7 layers). When using the IL 1-*n*-butyl-3-methylimidazolium hexafluorophosphate, Shang *et al.* exfoliated natural graphite by sequential mechanical grinding and sonication into graphene sheets of 2–5 layers.³¹ Another approach was used by Matsumoto *et al.*, applying a polymeric IL with the hexafluorophosphate anion.³² Microwave irradiation decomposed this anion under the formation of HF molecules, which intercalated within the graphite galleries and promoted exfoliation.

Although significant progress has been achieved in the preparation of graphene, a simple and high-yielding procedure for the large-scale production of cheap defect-free single- or few-layer graphene with large area and smooth edges remains a challenge.²⁶ As this seems being the main requisite to explore the full potential of graphene in the development of high-tech applications,³³ this study addresses the development of a simple one-step procedure for the preparation of graphene from the inexpensive untreated graphite ore. For the first time, graphite ore has been completely delaminated, treating an IL containing biphasic solvent system with cavitation in a pressurized ultrasonic reactor. This allowed not only obtaining defect-free graphene, but also enabled the facile segregation of the graphene from the mineral impurities.

Experimental

Materials

A crystalline graphite ore (carbon content of 48 wt%; mined in Lazec – situated in the Southbohemian Moldanubicum region) and a natural graphite powder (carbon content of 96 wt% and flake diameter in the range of 3–30 µm) were kindly provided by Koh-i-noor Grafite, Ltd., Czech Republic. 1-*n*-Butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide (BMImNTf₂; purity ≥ 98%) and 1-octanol (C₈H₁₇OH; purity ≥ 99.5%) were purchased from Sigma-Aldrich. Dichloromethane (CH₂Cl₂; purity ≥ 99.5%) was supplied by Lach-Ner.

Graphite exfoliation in high-pressure ultrasound reactor (HP-US)

Graphite ore (0.3 g), together with the biphasic water (95 mL) and organic solvent (CH₂Cl₂ or C₈H₁₇OH, 5 mL) system, and IL BMImNTf₂ in the indicated quantity, was added to an ultrasound reactor and pressurized to 5 bar (UIP 2000hd, 20 kHz, 2000 W, Hielscher Ultrasonics GmbH). The reaction vessel was connected to a refrigerated recirculator, keeping the reaction temperature at ~10 °C. Three different sonication programs were applied, using in all cases 1.3 kW of sonication power: (i) 10 min of uninterrupted exposition, (ii) two 15 min expositions

intercalated with a 5 min interval (total sonication time: 30 min), and (iii) two 15 min and one 20 min expositions intercalated with two 5 min intervals (total sonication time: 50 min) (Fig. 1). Following the sonication process, the obtained suspensions were stored in glass vessels.

Atomic force microscopy (AFM)

A Dimension Icon Atomic Force Microscope (Bruker) was used to record the AFM images. A silicon tip on a nitride lever was employed for the measurement in ScanAsyst-air contact mode. Two methods were used to deposit the sample on a suitable support prior the measurement. (i) The majority of the samples were prepared by a spin-coating method; where the samples were pipetted (20–40 µL) onto a smooth mica support and spread over the substrate by rotation. (ii) The rest of the samples were prepared by depositing a drop on a glass microscope slide.

Transmission electron microscopy (TEM)

TEM samples were deposited onto copper TEM grids (300 mesh) coated with a holey carbon, washed few times with CH₂Cl₂ and imaged using a Tecnai G2 Spirit Twin at 120 kV (FEI).

High resolution transmission electron microscopy (HRTEM)

Samples for HRTEM were first diluted in CH₂Cl₂ and put into bath ultrasound for 5 min. Then, the diluted sample was deposited onto carbon-coated lacey TEM grid. The solvent was left to evaporate and the sample was dried under dynamic vacuum at 80 °C for 4 hours. HRTEM and selected area electron diffraction (SAED) were carried out using a FEI Talos transmission electron microscope operating at 120 kV.

X-ray diffraction (XRD)

Diffraction patterns of thin films on a silicon sample holder were measured using a diffractometer Bruker D2 equipped with a conventional X-ray tube (CuKα radiation, 30 kV, 10 mA). The following conditions were used: 0.6 mm primary divergence slit

Fig. 1 Photographic images of the graphite ore fragment used and the dispersions obtained before pressurized sonication in H₂O–CH₂Cl₂ (a) and after pressurized sonication in H₂O–CH₂Cl₂ (b) and in H₂O–C₈H₁₇OH (c) systems. Images (b) and (c) were taken 3 months after the vials were stored.

module width, Soler Module 2.5, 2 mm Airscatter screen module, 0.5 mm Ni Kbeta-filter, 5–90° range, 0.00405° steps; 0.3 s per step, and the LYNXEYE 1-dimensional detector. The crystallite size, interlayer spacing and number of C atom layers were calculated using the Debye–Scherrer equations.^{34,35}

Raman spectroscopy

The Raman spectra were taken on a DXR Raman microscope (Thermo Scientific) using a 10× objective lens (Olympus microscope) with a 532 nm (3 mW) laser excitation, being the average of 32 two-second scans. Graphene/graphite dispersions were dropped on plasma-treated microscopic glasses, 3 times washed with CH₂Cl₂ and dried at 60 °C.

X-ray photoelectron spectroscopy (XPS)

Thin films were prepared from CH₂Cl₂-diluted graphene/graphite dispersions on plasma-treated microscopic glasses, followed by drying under vacuum at 80 °C. The XPS measurements were carried out on a K-Alpha⁺ XPS spectrometer (ThermoFisher Scientific) operating at a base pressure of 1.0×10^{-7} Pa. The data acquisition and processing were performed using the Thermo Advantage software. All samples were analyzed using a microfocused, monochromated Al K α X-ray radiation (400 μ m spot size) with a pass energy of 200 eV for survey and 50 eV for high-energy resolution core level spectra. The X-ray angle of incidence was 30° and the emission angle was along the surface normal. The K-Alpha charge dual compensation system was employed during analysis, using electrons and low-energy argon ions to prevent any localized charge build-up. The obtained high-resolution spectra were fitted/deconvoluted with Voigt profiles (binding energy uncertainty: ± 0.1 eV). The analyzer transmission function, Scofield sensitivity factors, and effective attenuation lengths (EAL) for photoelectrons were applied for quantification. EAL were calculated using the standard TPP-2M formalism. All spectra were referenced to the C 1s peak attributed to C–C, C–H at 285.0 eV binding energy, which were controlled by means of the well-known photoelectron peaks of metallic Cu, Ag, and Au.

Results and discussion

Biphasic solvent systems, composed of organic (CH₂Cl₂ or C₈H₁₇OH) and water phase, were used as medium for graphite ore delamination to graphene sheets in a high-pressure ultrasound reactor (HP-US). At the same time, the graphite flakes were isolated from the country rock due to the differences in surface tension. Contrary to the conventional flotation techniques where only the mineral impurities attached to the surface of graphite flakes are removed,³⁶ in this system the “intercalated” ash that resides between adjacent graphene layers' stack is separated from the formed graphene sheets. As demonstrated in Fig. 1, the purified graphene sheets were mainly trapped on water–organic solvent interphase, covered the organic solvent–glass interface and partially located in the organic phase, whilst the mineral impurities remained in the water phase. The use of organic solvents with different densities

allowed choosing where the phase with obtained graphene was *i.e.*, CH₂Cl₂ is denser than water and graphene stayed from the interphase to the lower phase (Fig. 1b), while C₈H₁₇OH is less dense than water trapping graphene from interphase to the upper phase (Fig. 1c).

The influence of the particles wettability by the liquids is a first order parameter in the particles adsorption behavior at the fluid–fluid interphase. When omitting any kinetic effects, the preferential adsorption of the formed graphene particles on the water–organic solvent interphase, in the equilibrium state, is governed by thermodynamics' tendency to minimize the interfacial energy.³⁷ The knowledge of interfacial tensions between both liquids and between liquids and graphene should be sufficient to calculate wettability parameter and to predict the graphene's location in the biphasic system. The calculated wettability parameter predicts the graphene location at the interphase, which was confirmed by the experiments (the details are given in the ESI†). Preferentially, high aspect ratio planar graphene sheets adsorb at the liquid–liquid interphase, which has also been described in the literature for water–chloroform³⁸ and water–heptane³⁹ systems. Interestingly, no sedimentation and re-aggregation could be observed in the dispersions after storage for 3 months (Fig. 1), indicating that the interfacial graphene layers were very stable and energetically more favorable than restacking and agglomeration of the graphene sheets.³⁸

Imidazolium IL have demonstrated huge potential as medium in the unrolling of MWCNT and the exfoliation of graphite.⁴⁰ Especially, the hydrophobic IL BMImNTf₂ appears being extremely compatible with these approaches, acting not only as a surfactant for carbon nanobjects through π – π stacking (graphene–imidazolium cation),⁴⁰ but also as the “unrolling/exfoliating” agent when applying specific sonication conditions.⁴⁰ In the current study, a similar effect of BMImNTf₂ was observed on the graphite ore exfoliation and dispersion when applied as additive. The delamination kinetics in the absence and presence of 0.3 wt% of BMImNTf₂ were investigated using TEM and XRD techniques (Fig. 2).

According to the TEM images, no graphite ore delamination was observed after 10 min of sonication in the absence of IL (Fig. 2a). For this case, the total sonication time had to be prolonged up to 50 min (Fig. 2c) to produce graphene sheets. This exfoliation progress was also observed by XRD (Fig. 2). The graphite diffraction pattern contains a typical (002) reflection at $2\theta = 26.4^\circ$, corresponding to the basal distance of 0.336 nm. Its diffraction intensity (002) decreased progressively after 30 min and 50 min of pressurized sonication (Fig. 2). On the other hand, the IL containing system showed a much more efficient graphite delamination, as graphene sheets were already formed after 10 min of sonication (Fig. 2d). The XRD diffractogram is in agreement with this observation, presenting already a drastic decrease in the intensity of the (002) diffraction peak after 10 min (Fig. 2). After 30 min, the (002) peak intensity was much lower compared to those measured from samples without IL, confirming the beneficial role of BMImNTf₂ in this process.

In spite of the samples dilution and washing with CH₂Cl₂ prior to TEM analyses, the presence of IL (aggregated gray spots) on the graphene sheets was observed. This is in agreement with

Fig. 2 TEM images and XRD diffractograms of dispersed graphite-graphene after 10 min (a), 30 min (b) and 50 min (c) sonication in the $\text{H}_2\text{O}-\text{CH}_2\text{Cl}_2$ system, and after 10 min (d), 30 min (e) and 50 min (f) sonication in the $\text{H}_2\text{O}-\text{CH}_2\text{Cl}_2$ -IL system. The XRD pattern of pristine graphite ore (G_m) is given for comparison.

the strong π - π interaction between the imidazolium ring of BMImNTf₂ and the graphene surface.^{10,29,30,41} The physical adsorption of IL on the graphene sheets surface was further investigated using XPS (Table 1). An increase in the nitrogen content and the appearance of sulfur and fluorine indicated the BMImNTf₂ presence on the graphene surface. Notably, the N : F : S ratio (considering the nitrogen increment due to the presence of IL) was 1.5 : 3.0 : 1.1 which was in excellent agreement with the expected theoretical ratio for BMImNTf₂ (1.5 : 3.0 : 1.0). Moreover, the heteroatom-carbon proportion obtained corresponds to that of the IL's molecular composition. Considering that BMImNTf₂ has the molecular formula $\text{C}_{10}\text{H}_{15}\text{F}_6\text{N}_3\text{O}_4\text{S}_2$, the expected C1s : O1s ratio of neat IL is 2.5. The obtained C1s : O1s for exfoliated graphite without and with IL were 4.57 and 2.64, respectively. As a consequence, it is reasonable to infer that most of the atomic contribution obtained by XPS was from the IL, thus explaining the increased O1s values and excluding the possibility of an oxidative process. The high-resolution C1s, N1s, S2p and F1s spectra of exfoliated graphite ore can be found in the ESI (Fig. S1†).

The degree of graphite exfoliation was determined by AFM (Fig. 3). Graphene flakes with an average thickness of 1–1.5 nm were obtained after pressurized sonication for 50 min without IL addition (Fig. 3c and f). When IL was added, graphene flakes with a thickness of <1.5 nm were produced within a much shorter sonication time of 10 min (Fig. 3a and d). Additional sonication (30 min in total) led to further thickness reduction of the

Table 1 XPS elemental compositions of exfoliated graphite ore obtained in the absence or presence of IL

Orbital	Exfoliated graphite ore		Exfoliated graphite ore + IL	
	Atomic%	Weight%	Atomic%	Weight%
S2p	0.0	0.0	1.1 ± 0.3	6.1 ± 0.6

N1s	0.8 ± 0.1	0.9 ± 0.1	2.3 ± 0.2	2.7 ± 0.2
O1s	17.8 ± 0.3	22.4 ± 0.3	26.4 ± 2.6	25.3 ± 3.0
F1s	0.0	0.0	3.0 ± 0.6	5.2 ± 0.9

graphene flakes to ~ 1.0 nm (Fig. 3b and e). Considering the thickness of single graphene layer (0.335 nm),⁴² 10 min and 30 min of pressurized sonication in the presence of IL led to graphene flakes with less than 5 and 3 layers, respectively. As the XPS analyses confirmed the presence of IL on the graphene surfaces (Table 1), their presence on the graphene sheets, as well as between the mica substrate and graphene sheets, cannot be excluded. Thus, the amount of graphene layers could in fact be smaller, indicating the formation of bilayers and monolayers. Furthermore, Hernandez *et al.* observed on AFM images thicker graphene monolayers than expected ($1\text{--}2$ nm instead of 0.3 nm).¹⁹ Generally, the thicknesses ≤ 1 nm determined from AFM height profiles are consistent with the formation of graphene.^{43–45}

The AFM study provided further information about the dimensions of the obtained graphenes. IL-assisted pressurized sonication produced after 10 min graphene sheets with much larger lateral dimensions (average diameter of 1100 ± 350 nm) compared to those obtained after 50 min in an IL-free system (average diameter of 380 ± 75 nm) (Fig. 3). This reduction in the lateral dimensions could indicate transversal breakage due to a too long exposition to intense cavitation.⁴⁶ The IL seems to help dissipating the excessive cavitation energy, since a similar phenomenon of graphene sheets lateral size reduction was only observed after 50 min of exposition, and in a much less intense manner (Fig. 2f).

The quality of the graphene sheets produced by the best evaluated procedure (30 min sonication in the presence of IL) was further evaluated by TEM (Fig. 4). Confirming the previous characterizations, mostly few-layers (Fig. 4a) and monolayer (Fig. 4b) graphene were formed. HRTEM (Fig. 4c) and two-dimensional fast Fourier transform (FFT) (Fig. 4d) images of the formed layers showed sets of district spots at 0.21 and 0.12 nm, which correspond to periodic hexagonal structure of AB Bernal stacked few-layer graphene.⁴⁷ The selected-area electron diffraction pattern taken from Fig. 4b is displayed in Fig. 4e, and the diffracted intensity taken along the

$(1\text{--}210)\text{--}(0\text{--}110)\text{--}(-1010)\text{--}(-2110)$ axis for this pattern is displayed in Fig. 4f. The inner peaks, $(0\text{--}110)$ and (-1010) , were more intense than the outer ones, $(1\text{--}210)$ and (-2110) , confirming the presence of a graphene monolayer in Fig. 4b.^{19,48} Besides, all observed areas seemed to be free of structural defects, evidencing that this exfoliation procedure was nondestructive. In the case of the systems with IL, the sheet edges also tended to bend (Fig. 3b) and crumple (Fig. 4a). Moreover, HRTEM images showed regions where fringes were observed, which indicated local curvature of the sheets.⁴⁹

The exfoliating experiments were also successfully performed when the $\text{H}_2\text{O}\text{--}\text{C}_8\text{H}_{17}\text{OH}$ biphasic system was used. As in the case of $\text{H}_2\text{O}\text{--}\text{CH}_2\text{Cl}_2$, BMImNTf₂ accelerated the whole exfoliation process. The intensity of the XRD 002 peak ($2\theta = 26.5$) decreased to less than 1% of its initial value after 30 minutes of pressurized sonication, indicating structural disordering and graphite exfoliation,³² in a slightly lower degree when compared to the $\text{H}_2\text{O}\text{--}\text{CH}_2\text{Cl}_2$ system (Fig. S2†). HRTEM images confirmed the formation of few-layers thick graphene sheets (Fig. S3†).

Raman spectroscopy is another important tool to determine the graphene quality. Fig. S4† shows the Raman spectra of bulk graphite ore and cast films from the graphene suspensions (without and with BMImNTf₂). Graphitic materials typically involve three bands; (i) the D-band (~ 1350 cm⁻¹), (ii) the G-band (~ 1580 cm⁻¹) and (iii) the 2D-band (~ 2700 cm⁻¹).⁵⁰ The D/G band intensity ratio (I_D/I_G) is often used for determining the graphene's degree of structural defects.⁵¹ Thus, a smaller I_D/I_G ratio means a lower number of defects and disorders in the graphitic structure, comprising the disorders caused at the edges of the platelets;⁵² therefore, the D-band intensity is influenced by the flake size.^{26,53} All prepared graphene films showed I_D/I_G ratio identical to the one of the pristine graphite ore (*ca.* 0.15, Table S2†), confirming the high structural integrity of the produced graphene sheets.³²

Commercial powdered natural graphite, extracted from the graphite ore by a conventional treatment, was also applied in

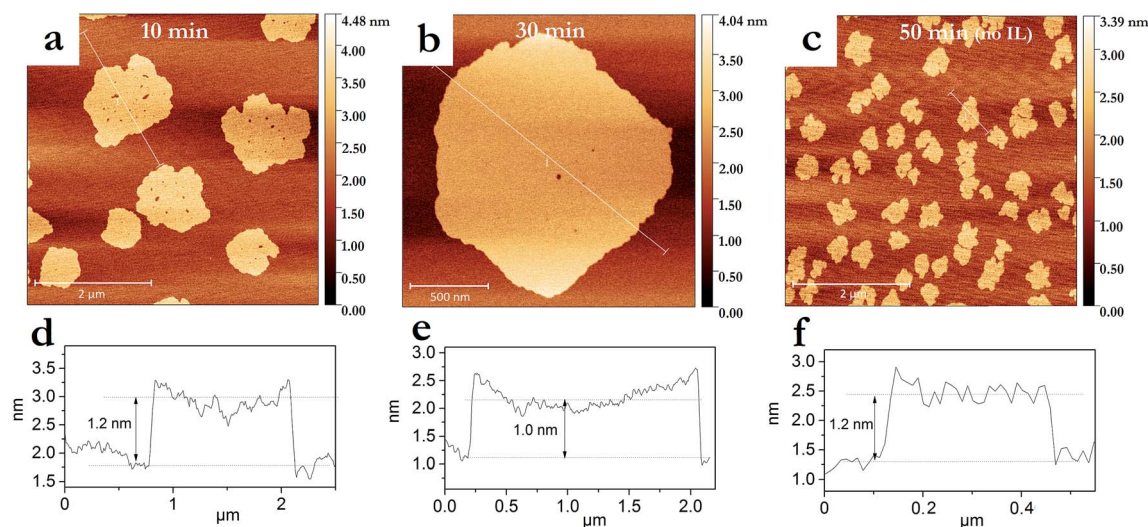

Fig. 3 AFM topology images of graphene sheets obtained after 10 min (a) and 30 min (b) pressurized sonication in the $\text{H}_2\text{O}\text{--}\text{CH}_2\text{Cl}_2\text{--IL}$ system, and (c) 50 min of pressurized sonication in the $\text{H}_2\text{O}\text{--}\text{CH}_2\text{Cl}_2$ system. The graphs (d)–(f) are the height profiles along the lines displayed in (a)–(c), respectively.

Fig. 4 Electron microscopy of graphene sheets obtained after 30 min HP-US in $\text{H}_2\text{O}-\text{CH}_2\text{Cl}_2$ in the presence of IL. TEM micrographs of (a) few-layers and (b) monolayer graphene; HRTEM micrograph (c) of a few-layers graphene taken from (a); two-dimensional FFT (d) of few-layers graphene taken from (a); electron diffraction patterns (e) of monolayer graphene taken from (b); diffracted intensity (f) taken along the $(1-210)-(0-110)-(-1010)-(-2110)$ axis from the pattern shown in (e).

the developed method and used as a comparison to the direct graphite ore exfoliation. The same pressurized sonication time (30 min) was sufficient to completely delaminate the powdered natural graphite in the biphasic $\text{H}_2\text{O}-\text{CH}_2\text{Cl}_2$ system containing 0.3 wt% of BMImNTf₂. The XRD pattern (Fig. S2[†]), TEM images and SAED (Fig. S5[†]) gave evidence that few-layers and monolayer graphene sheets were also formed. The similar graphene

sheets obtained, for both graphite ore and commercial powdered graphite, evidence the effectiveness of the process and highlight the advantages of a direct processing of the graphite ore.

Most interestingly, when a higher amount of CH_2Cl_2 (50 v%) was added to the process a different behavior was observed after 30 min of sonication. Macroporous swelled species with

Fig. 5 Microscopic images of the crumpled graphene-graphite species formed by biphasic pressurized sonication procedure at higher CH_2Cl_2 content; TEM image the general morphological aspect (a) and higher magnification of the "macroporous" (b) and "pine cone-like" (c) species formed. AFM topological image (d) and height profile (e) of a swelled graphene bilayer.

micrometric lateral dimension were formed in high yield (Fig. 5a). These seem to be constituted by few layers of crumpled graphene, forming two main types of structure; (i) large macroporous segments (Fig. 5b), and (ii) pine cone-like structures⁵⁴ formed by few layers of entangled and crumpled graphene (Fig. 5c). These structures were probably created due to the more intensive intercalation of IL-CH₂Cl₂ in between graphite galleries. As this phenomenon occurred exclusively with the IL-CH₂Cl₂ system, it seems to be a synergistic solvent-coupling agent effect. In Fig. 5d and e, AFM evidenced the formation of a graphene bilayer (~1 nm thick) with swollen central regions (2–3 nm thick), indicating that the swelling could be due to cavitation induced bubble formation from the intercalated IL-CH₂Cl₂. The two different structures formed could be a result of different local sheet size and chemical composition. The phase transition between a flat-membrane phase and the crumpled phase has been reported to have a notable dependence on the size, functionalization and defects of the graphene sheets.⁵⁵ Thus; the predominant presence of layered crumpled graphene structures was also an indication of the small content of sheet defects.

Conclusions

The pressurized sonication of a biphasic system represents a cheap and effective method for the exfoliation of graphite ore into few-layers graphene. This reaction set-up avoids the need of a centrifugation purification procedure, as the mineral impurities originated from the graphite ore are collected in the water phase or settle down at the bottom, whilst the produced graphene sheets are located at the liquid–liquid interface and in the organic phase. The addition of IL (BMImNTf₂) considerably reduced the exfoliation time and produced graphene sheets with much larger lateral dimensions. Although preliminary, also a prospective, simple and straightforward method for the controlled production of crumpled graphene materials has been demonstrated. Since these processes produce graphene sheets with non-covalently bonded BMImNTf₂ on the surface, the modified graphene species could be used in a vast range of materials applications without altering the pristine graphene characteristics. The system optimization and the role of different ionic liquids into the final materials' morphology are an active subject of our group and will be explored in details in further publications.
