A monometallic lanthanide bis(methanediide) single molecule magnet with a large energy barrier and complex spin relaxation behaviour†

Matthew Gregson,‡a Nicholas F. Chilton,‡a Ana-Maria Ariciu,b Floriana Tuna,b Iain F. Crowe,c William Lewis,d Alexander J. Blake,d David Collison,a Eric J. L. McInnes,b Richard E. P. Winpenny*a and Stephen T. Liddle*a

We report a dysprosium(ii) bis(methanediide) single molecule magnet (SMM) where stabilisation of the highly magnetic states and suppression of mixing of opposite magnetic projections is imposed by a linear arrangement of negatively-charged donor atoms supported by weak neutral donors. Treatment of \([\text{Ln(BIPMTMS)(BIPMTMSH)}] [\text{Ln} = \text{Dy}, \text{Y}, \text{1Y}]\) \(\text{BIPMTMS} = (\text{C(PPh}_2\text{NSiMe}_3)_2)_2\); \(\text{BIPMTMSH} = (\text{HC(PPh}_2\text{NSiMe}_3)_2)_2\) \(\text{THF}\) afforded \([\text{Ln(BIPMTMS)}] [\text{K(18C6)(THF)}] [\text{Ln} = \text{Dy}, \text{2Dy}; \text{Y}, \text{2Y}]\). AC magnetic measurements of \(\text{2Dy}\) in zero DC field show temperature- and frequency-dependent SMM behaviour. Orbach relaxation dominates at high temperature, but at lower temperatures a second-order Raman process dominates. Complex \(\text{2Dy}\) exhibits two thermally activated energy barriers \(U_{\text{eff}}\) of 721 and 813 K, the largest \(U_{\text{eff}}\) values for any monometallic dysprosium(ii) complex. Dilution experiments confirm the molecular origin of this phenomenon. Complex \(\text{2Dy}\) has rich magnetic dynamics; field-cooled (FC)/zero-field cooled (ZFC) susceptibility measurements show a clear divergence at 16 K, meaning the magnetic observables are out-of-equilibrium below this temperature, however the maximum in ZFC, which conventionally defines the blocking temperature, \(T_b\), is found at 10 K. Magnetic hysteresis is also observed in 10% field-cooled (ZFC) measurements at these temperatures. \(\text{Ab initio}\) calculations suggest the lowest three Kramers doublets of the ground \(\text{6H}_{15/2}\) multiplet of \(\text{2Dy}\) are essentially pure, well-isolated \(\pm 15/2\), \(\pm 13/2\) and \(\pm 11/2\) states quantised along the \(C=\text{Dy}=\text{C}\) axis. Thermal relaxation occurs via the \(4^{th}\) and \(5^{th}\) doublets, verified experimentally for the first time, and calculated \(U_{\text{eff}}\) values of 742 and 810 K compare very well to experimental magnetism and luminescence data. This work validates a design strategy towards realising high-temperature SMMs and produces unusual spin relaxation behaviour where the magnetic observables are out-of-equilibrium some 6 K above the formal blocking temperature.

Introduction

Proposals have been made for devices employing the quantum effects of molecular magnets,\textsuperscript{1–3} and many remarkable experimental results have been reported involving single molecule magnets (SMMs).\textsuperscript{4–6} SMMs are molecules that show slow relaxation of magnetisation, which can lead to observation of magnetic hysteresis of a molecular origin.\textsuperscript{7} These addressable magnets operating at the scale of a few nm lay the groundwork for new, potentially revolutionary quantum-based devices; however until SMMs operate at much higher temperatures their exploitation seems unlikely.

Many interesting SMMs have been reported based on a single lanthanide centre,\textsuperscript{8} and theoretical developments for their understanding are progressing at a rapid pace.\textsuperscript{9–11} Recently a design principle for a high-temperature SMM was proposed, in the form of a linear two-coordinate lanthanide complex.\textsuperscript{12,13} A linear arrangement of negatively charged donor atoms imposes a strong and purely axial ligand field (LF) potential, stabilising the maximal angular momentum projections of 4f ions with oblate electron densities such as dysprosium(ii).\textsuperscript{14–16} This would result in electronic states that are widely separated in energy,
leading to huge energy barriers, $U_{\text{eff}}$, for thermal relaxation processes. Furthermore, owing to the high symmetry of the LF potential there should be no mixing between components of opposite magnetic projection, therefore disallowing short-cuts through or under the barrier.$^{17}$ Our design strategy is orthogonal to that required for 4f ions whose maximal angular momentum functions have prolate electron densities such as erbium($m$), where equatorial LF potentials are required; this alternative approach has recently yielded an excellent result in the form of [Er(COT)$_4$]$_{2-}$. We previously calculated that in a real system, where the symmetry is likely to be lower than ideal, even a near-axial LF imposed by anionic donors should be strong enough to produce large $U_{\text{eff}}$ barriers.$^{13}$ This remains experimentally unproven, but provides a promising direction towards high temperature SMMs.

Simple electrostatic considerations imply that the strength of the axial LF depends on the charge on the donor atoms on the axis, and hence we proposed that the use of dianionic methanediide complex [Zr{C(PMe$_2$NSiMe$_3$)$_2$}], where the two ligands are orthogonal due to the molecular symmetry is considered. Our design strategy is orthogonal to that required for 4f ions whose maximal angular momentum functions have prolate electron densities such as erbium($m$), where equatorial LF potentials are required; this alternative approach has recently yielded an excellent result in the form of [Er(COT)$_4$]$_{2-}$. We previously calculated that in a real system, where the symmetry is likely to be lower than ideal, even a near-axial LF imposed by anionic donors should be strong enough to produce large $U_{\text{eff}}$ barriers.$^{13}$ This remains experimentally unproven, but provides a promising direction towards high temperature SMMs.

Simple electrostatic considerations imply that the strength of the axial LF depends on the charge on the donor atoms on the axis, and hence we proposed that the use of dianionic methanediide would optimise $U_{\text{eff}}$. However, such complexes present a significant synthetic challenge; four decades after the first proposal of a lanthanide alkylidene, such a species remains elusive, let alone realising a bis(alkylidene) complex. The stabilisation of a two-coordinate lanthanide bis(dicarbonyl) complex clearly represents a major challenge, even before control of molecular symmetry is considered. Our first step towards the synthesis of such a difficult target is to consider a complex stabilised by weak equatorial donors in a pincer framework. There has been a significant amount of work in recent years where the stabilisation of lanthanide complexes with carbanion donors is achieved with phosphorus substituents, where both mono- and di-anionic donors are known. Seeking inspiration, we noted that Cavell et al. reported the bis(methanediide) complex [Zr(C(PMe$_2$NSiMe$_3$)$_2$)]$_2$, where the two ligands are orthogonal due to the ‘locking’ effect of the imino arms to avoid steric clashing. Such an arrangement is particularly important in the design of a SMM – whilst two-coordinate complexes are ideal, if stabilising donors atoms must be present they should at least be symmetrically disposed.

Here we report the synthesis, structure, theoretical characterisation and magnetic studies of a bis(methanediide) complex of dysprosium($m$) which has a $U_{\text{eff}}$ value of 813 K, the largest for any monometallic dysprosium($m$) complex. This complex also possesses rich magnetisation dynamics where out-of-equilibrium magnetisation is observed below 16 K yet $T_B$ appears to be 10 K. Although the bis(methanediide) complex is not a two-coordinate linear system, it is clear that there is significant charge accumulation along the C–Dy–C axis which effectively mimics the linear arrangement we ultimately seek. Thus, this work experimentally validates our proposition that a linear arrangement of negative charges in a dysprosium($m$) complex should lead to very large energy barriers to magnetic relaxation, and provides a promising direction to making high-temperature SMMs a reality.

Results

Synthesis and characterisation

The route to a bis(methanediide) dysprosium($m$) complex is shown in Scheme 1. Treatment of [Dy(CH$_2$Ph)$_3$(THF)$_2$] with two equivalents of BIPMTMSH$_2$ [BIPMTMSH$_2$ = H$_2$C(PPh$_2$-NSiMe$_3$)$_2$] in toluene produces an orange solution, which when briefly heated fades to yellow. Work-up and recrystallisation from toluene affords colourless crystals of the mixed methanediide–methanide complex [Dy(BIPMTMS)(BIPMTMSH)] (1Dy) in 63% isolated yield. Alternatively, treatment of [Dy(BIPMTMS)(CH$_2$Ph)(THF)] with one equivalent of BIPMTMSH$_2$ also affords 1Dy in 63% yield. Complex [Dy(BIPMTMS)(CH$_2$-Ph)(THF)] was reported previously by us, but was not structurally authenticated; here we report its solid state structure (see ESI†). The orange colour during preparations is most likely due to the intermediate formation of [Dy(BIPMTMS)(CH$_2$Ph)(THF)] that effects metallaion of free BIPMTMSH$_2$ when heated. We previously showed that early, large lanthanides (La–Gd) spontaneously form the mixed methanediide–methanide combination irrespective of reactant ratios, presumably via highly reactive [Ln(BIPMTMS)(CH$_2$Ph)(THF)] complexes due to the large metal size, whereas the later, smaller lanthanides like Dy and Er form isolable methanediide–benzyl combinations. The formulation of 1Dy is supported by IR, CHN, and Evans method magnetic moment ($\mu_{\text{eff}} = 11 \mu_B$), but the $^1$H NMR spectrum is broad and uninformative due to the paramagnetic Dy$^{III}$ ion.

Scheme 1 Synthesis of 1Dy/Y and 2Dy/Y. The reaction of the respective lanthanide tribenzyl tris(tetrahydrofuran) complex with two molar equivalents of the parent methane pro-ligand produces the mixed lanthanide methanediide–methanide complexes 1Dy (dysprosium) or 1Y (yttrium) with concomitant elimination of three molar equivalents of toluene by deprotonation. Alternatively, the reaction of the methanediide–benzyl precursor with one equivalent of methane pro-ligand gives the same complexes with elimination of one equivalent of toluene by deprotonation. Treatment of 1Dy or 1Y with benzyl potassium in THF in the presence of 18-crown-6 ether (18C6) effects deprotonation of the remaining methanide hydrogen to eliminate toluene and produce the bis(methanediide) formulation at the lanthanide. The 18C6 encapsulates the potassium ion which is further coordinated by two molecules of THF from the solvent to form a solvent separated ion pair.
With 1Dy in hand, we prepared the target bis(methanediide) derivative. Treatment of 1Dy with benzyl potassium in THF gave an orange suspension, which yielded a yellow solution after stirring. Following addition of 18-crown-6 ether (18C6) and concentration, yellow crystals of the bis(methanediide) complex \([\text{Dy(BIPMTMS)}(\text{CH}_2\text{Ph})(\text{THF})])\) and in six-coordinate \(2\text{Dy}\) were obtained in 43% isolated yield. The identity of \(2\text{Dy}\) is supported by IR, CHN, and Evans method magnetic moment data \(\mu_{\text{eff}} = 11 \mu_B\); however, as for 1Dy the \(^1\text{H}\) NMR spectrum of \(2\text{Dy}\) is uninformative. For the purposes of doping \(2\text{Dy}\) into a diamagnetic host we prepared the yttrium bis(methanediide) analogue \([\text{Y(BIPMTMS)}_2][\text{K(18C6)(THF)}_2]\)–2THF (2Y) in 60% yield from \([\text{Y(BIPMTMS)}][\text{BIPMTMSH}]) (1Y). The interaction of the methanediide centres in 2Y with yttrium can be seen in the \(^{13}\text{C}\) NMR spectrum, which exhibits a single triplet of doublets at 53.70 ppm (\(J_{\text{PC}} = 210.86 \text{ Hz}; J_{\text{YC}} = 3.07 \text{ Hz}\)) showing that the methanediides are magnetically equivalent on the NMR timescale; this can be compared to the \(^{13}\text{C}\) NMR spectrum of 1Y which exhibits a triplet at 19.87 ppm (\(J_{\text{PC}} = 114.25 \text{ Hz}\)) and a triplet of doublets at 66.50 ppm (\(J_{\text{PC}} = 171.76 \text{ Hz}; J_{\text{YC}} = 6.90 \text{ Hz}\)) for the methanediide and methanediide centres respectively. This suggests a significant interaction between the yttrium and methanediide centres in 2Y, and by inference a similar situation for the dysprosium and methanediide centres in 2Dy, which is important for generating a largely axial LF at dysprosium.

Structural characterisations

The solid state structures of 1Dy and 2Dy were determined by X-ray crystallography and are illustrated in Fig. 1. The yttrium analogues can be found in the ESI.† Complex 1Dy crystallises as discrete monomers where the dysprosium centre is six-coordinate. The C=C-Dy–C angle is 158.25(6)°, and the N–Dy–N angles are 129.51(5)° and 110.51(5)° for the methanediide and methanide ligands, respectively. The Dy=C and Dy–C bond lengths are 2.3640(17) and 2.9001(18) Å, respectively, which reflects the formal double and single bond character of these linkages. The Dy–N distances are longer in the methanediide [range: 2.4387(15)–2.4786(15) Å] than the methanide [range: 2.3903(15)–2.4092(15) Å]. The methanediide centre adopts an essentially T-shaped planar geometry [\(\Sigma < \approx 355.06(16)\)] whereas the methanide is puckered to accommodate the hydrogen atom. Complex 1Dy does not approach the linear arrangement of highly charged donor atoms that we seek.

Complex 2Dy crystallises as a solvent separated ion pair and there are no significant contacts between the [Dy(BIPMTMS)(THF)])\(^{11}\) anion and the \([\text{K(18C6)(THF)}_2]\)\(^{11}\) cation components. Complex 2Dy has the on-axis C=C–Dy=C arrangement of highly charged donor atoms required to test our proposal for high-temperature SMMs. The dysprosium ion is six-coordinate and the C=C–Dy=C angle is almost linear at 176.6(2)°. The methanediide centres adopt planar T-shaped geometries [av. \(\Sigma < \approx 357.1(6)\)] and, importantly, the two C(PN)\(_2\)Dy planes are disposed essentially orthogonal to each other [89.47(12)]°]. The Dy=C bond distances of 2.434(6) and 2.433(6) Å are statistically identical, and longer than the Dy=C distance of 2.364(2) Å in four coordinate [Dy(BIPMTMS)(CH\(_2\)Ph)(THF)] and in six-coordinate 1Dy, reflecting the trans-disposition of the two methanediide centres and the electron-rich, anionic formulation of the dysprosium fragment in 2Dy. The Dy–N bond lengths in 2Dy average 2.461(9) Å, which is consistent with the analogous methanediide-derived Dy–N bond lengths in 1Dy. All other bond distances and angles in the (BIPMTMS){\(^2\)} are unexceptional for this ligand in its dianionic state.\(^{22–24}\)

Static and dynamic magnetism

The magnetic properties of 1Dy and 2Dy were measured as neat polycrystalline powders dispersed in eicosane and flame sealed in a quartz NMR tube. The room temperature value of \(\chi_m^T\) of
2Dy is 13.5 cm$^3$ mol$^{-1}$ K, around 10% lower than expected for a free Dy$^{3+}$ ion (14.2 cm$^3$ mol$^{-1}$ K, Fig. 2). Measuring in-field in a cooling cycle [FC(c)], $\chi_m T$ is weakly temperature dependent to 100 K below which the moment starts to fall gradually reaching a value of 12.6 cm$^3$ mol$^{-1}$ K by 50 K, suggesting that at this temperature only the $|\pm 15/2\rangle$ doublet is populated. At 16 K $\chi_m T$ decreases precipitously, where equilibrium population cannot be achieved due to the barrier to magnetisation reversal (see below). Magnetisation ($M$) versus field ($H$) curves at 1.8 K saturate at a value of $\approx 5.1 \mu_B$, confirming a well isolated $|\pm 15/2\rangle$ ground state.

AC magnetic measurements performed on 2Dy in zero DC field show temperature and frequency dependent behaviour, characteristic of slow magnetic relaxation over two thermal barriers, Fig. 3a. Fitting these data to the generalised Debye equation yields temperature dependent relaxation times, Fig. 3b and c. The strong linear dependence of $\ln(\tau)$ at high temperatures is indicative of a dominant Orbach relaxation mechanism, whilst at lower temperatures its curvature suggests competing relaxation processes are active. As a temperature independent regime is not reached, this cannot be attributed to QTM and we therefore interpret this as a second order Raman process.§

---

**Fig. 2** (a) Magnetic susceptibility temperature product for 2Dy versus temperature measured in a 0.1 T field (field-cooled). Note that the ab initio data was scaled by 0.968 to reproduce the experimental values above 200 K. (b) Magnetisation hysteresis of 2Dy measured at 1.8 K with a sweep rate of 3.5 mT s$^{-1}$. Saturation of the magnetisation at a value of 5.1 $\mu_B$ is indicative of a $|\pm 15/2\rangle$ ground state.

**Fig. 3** (a) In-phase $\chi'$ (top) and out-of-phase $\chi''$ (bottom) AC magnetic susceptibility as a function of frequency in zero DC field for 2Dy. Solid lines are fits to the generalised Debye model. (b) Natural logarithm of the relaxation times for the two barriers observed in 2Dy as a function of reciprocal temperature. Red lines are fits to eqn (2), see text for parameters. (c) Cole plot for 2Dy recorded at different temperatures under zero DC field with an AC field of 1.55 Oe, at frequencies between 0.1 and 1400 Hz. Solid black lines are fits to the generalised Debye equation.
\[
\frac{1}{\tau} = \frac{1}{\tau_0} e^{-\nu_{in}/T} + CT^n
\]  

(1)

Fitting the two data sets with eqn (1) yields \( U_{\text{eff}}(1) = 721(1) \) K (501 cm\(^{-1}\)), \( \tau_0(1) = 1.11(3) \times 10^{-12} \) s, \( C(1) = 3.01(7) \times 10^{-11} \) s \(^{-1}\) K \(^{-n}\), \( n(1) = 7\), \( \alpha(1) = 0.01 - 0.03\), \( U_{\text{eff}}(2) = 813(1) \) K (565 cm\(^{-1}\)), \( \tau_0(2) = 5.65(20) \) \times 10\(^{-13}\) s, \( C(2) = 3.55(10) \times 10^{-9} \) s \(^{-1}\) K \(^{-6}\), \( n(2) = 6\) and \( \alpha(2) = 0.11 - 0.21\). The values of \( \tau_0 \) are of the correct order of magnitude expected for an Orbach relaxation process over a large barrier \((\tau_0 \sim (10^{-5} \text{ to } 10^{-3})/U_{\text{eff}}(3))^{1/2}\) and the values of \( C \) and \( n \) are as expected for the second-order Raman process for Kramers ions.\(^{27}\) We have explored the possibilities that the measured relaxation data are due to the Raman process alone, or to a combination of two Orbach processes, but find that these cannot explain the data as the parameters required for such fits are physically unreasonable, see ESI and Fig. S1 and S2.\(^{\dagger}\) The same characteristic out-of-phase AC signals can be found in dilute samples (10% 2Dy@2Y and 3% 2Dy@2Y), Fig. S3,\(^{\dagger}\) therefore confirming the molecular origin of this phenomenon.

The blocking temperature \( T_B \) is conventionally defined as the maximum in the ZFC susceptibility;\(^{7}\) Gatteschi et al. have pointed out that for SMMs a second temperature, \( T_{\text{IRREV}} \), is also important which is the point where the FC and ZFC susceptibilities diverge, as this is the temperature below which the magnetic observables are out-of-equilibrium and show history dependent behaviour.\(^{7}\) For most SMMs \( T_B \) and \( T_{\text{IRREV}} \) are very similar, and observed differences have been assigned to a distribution of relaxation times.\(^{7}\) Another proposed definition of \( T_B \) is the temperature where the relaxation time is 100 s.\(^{7,18,28}\)

We have used DC and AC magnetic measurements to establish both \( T_B \) and \( T_{\text{IRREV}} \) for 2Dy. Magnetic hysteresis is observed in \( M(H) \) loops for 10% 2Dy@2Y to at least 10 K for a sweep rate of 3.5 mT s\(^{-1}\); the coercivity at 13 and 16 K is very small. Extrapolation of the fitted AC relaxation times for 2Dy gives a relaxation time of 100 s at 12 K. FC(\(c\))/zero-FC (ZFC) measurements for 2Dy diverge at temperatures up to 16 K (Fig. 4b), with the ZFC maximum at ca. 10 K, depending on the heating/cooling rates. Therefore while \( T_B \) for 2Dy is 10–12 K by conventional definitions, the magnetic observables are history dependent below 16 K. To investigate this further we have also measured FC(\(w\)); these data also diverge from FC(\(c\)) at temperatures up to 16 K depending on unusually, for any rate that we measured, the FC(\(w\)) data go above the FC(\(c\)) before reaching equilibrium. Such behaviour would normally be associated with a metastable state arising from the phenomenon of magnetostriction,\(^{29}\) but its origin here is unclear and will require extensive further studies.

Furthermore, the discrepancy of up to 6 K between \( T_B \) and \( T_{\text{IRREV}} \) usually explained as owing to a range of relaxation times, is very large and does not appear to have precedent in SMMs. Accounting for these two observations, we can only suggest that multiple relaxation processes are competitive at low temperatures, including Raman and QTM mechanisms, which gives rise to this strange behaviour.

There remains a significant, sweep-rate dependent, loss of magnetisation at zero-field in \( M(H) \) even at the lowest temperature measured (1.8 K), Fig. S4 and S5.\(^{\dagger}\) This drop at zero-field is less pronounced in the dilute samples, indicating that there is an intermolecular contribution to the relaxation, but that the blocking is due to individual molecules. Measurements of the decay of magnetisation as a function of time, Fig. S6,\(^{\dagger}\) on the dilute samples shows there is a significant magnetisation that is retained for a very long time; in the 1 : 20 sample \( M = 0.15 \mu_B \) after 10 hours. This is only 3% of the saturation magnetisation, but clearly some component of the system has a very long lifetime.

The \( \chi_mT \) of 1Dy is 13.7 cm\(^3\) mol\(^{-1}\) K at room temperature and is weakly temperature dependent until below 70 K where it starts to gradually fall, followed by a larger drop at very low temperatures (Fig. S7).\(^{\dagger}\) The \( M(H) \) at 1.8 K saturates at a value of \( \sim 5.2 \mu_B \) mol\(^{-1}\) (Fig. S8) which is indicative of a well isolated \( \pm 15/2 \) ground state. AC magnetic measurements
performed in zero DC field show temperature and frequency dependent behaviour above 10 K (Fig. S9†). Fitting these data to the generalised Debye equation (Fig. S10†), yields temperature dependent relaxation times which results in a linear ln(τ) vs. 1/T curve at high temperatures, whilst at lower temperatures we observe a transition to a temperature independent regime (Fig. S11†). This is indicative of a dominant Orbach relaxation mechanism at high temperature and QTM at lower temperatures. Application of an optimal 1 kG DC field can quench the temperature independent process (Fig. S9 and S12†) however the ln(τ) vs. 1/T plot still curves at lower temperatures (Fig. S11†). This curvature in the intermediate temperature regime also requires a second order Raman mechanism and we model the temperature dependent relaxation data for both zero field and 1 kG simultaneously with eqn (2), where the 1/τQTM term is omitted for the 1 kG relaxation data.

\[
\frac{1}{\tau} = \frac{1}{\tau_0} e^{-\frac{E_{\text{QTM}}}{T}} + C T^\alpha + \frac{1}{\tau_{\text{eff}}} \tag{2}
\]

The best-fit parameters are \( U_{\text{eff}} = 255(1) \text{ K} \) (177 cm\(^{-1}\)), \( \tau_0 = 3.55(9) \times 10^{-12} \text{ s} \), \( C = 1.46(3) \times 10^{-5} \text{ s}^{-1} \text{ K}^{-7} \), \( n = 7 \), \( \tau_{\text{QTM}} = 9.26(10) \times 10^{-3} \text{ s} \) and \( \alpha = 0.06-0.22 \). The values of \( \tau_0 \) are of the correct order of magnitude expected for an Orbach relaxation process over a large barrier and the values of \( C \) and \( n \) are as expected for the second order Raman process for Kramers ions.\(^{27}\)

**Theoretical characterisation**

Based on the X-ray crystal structures of \( 1\text{Dy} \) and \( 2\text{Dy} \), we performed *ab initio* calculations of the CASSCF/RASSI/SINGLE_ANISO variety with MOLCAS 7.8.\(^{30-32}\) The calculated \( \chi_{\alpha\beta} T \) vs. \( T \) plots for both compounds are almost identical to that obtained experimentally, save for the sub-16 K data for \( 2\text{Dy} \) (Fig. 2a and S7†), and require scaling factors of 0.981 and 0.968 for \( 1\text{Dy} \) and \( 2\text{Dy} \), respectively, to reproduce the data above 200 K. Such scaling factors are modest compared to other works.\(^{24}\) As predicted, the linear coordination mode of the two methanediide centres in \( 2\text{Dy} \) with a large build-up of negative charge on the axis ensures a large energy gap between the \( |\pm 15/2\) \) ground state and all other doublets (see Tables 1 and S1†). In further agreement with our expectations, the three lowest energy Kramers doublets of the ground \( ^6\text{H}_{15/2} \) multiplet of \( 2\text{Dy} \) are essentially the pure \( |\pm 15/2\) \), \( |\pm 13/2\) and \( |\pm 11/2\) states quantised along the main \( C=\text{Dy}=C \) axis. The result of this is that thermal relaxation via the second and third states is quenched. The fourth and fifth doublets are strongly mixed, and have main magnetic axes perpendicular to that of the ground state, allowing efficient relaxation (Fig. 5 and Tables S2 and S3†). They are calculated to lie at energies of 742 K and 810 K, respectively, which is in excellent agreement with the experimentally determined energy barriers of \( U_{\text{eff}}^{(1)} = 721 \text{ K} \) and \( U_{\text{eff}}^{(2)} = 813 \text{ K} \).

Whilst the RN\(^-\)P\((\text{R})_2\)\(^-\)C\(^2\)\(^-\)P\((\text{R})_2\)\(^-\)N\(^-\)R resonance form of the (BIPM\(^{\text{TMS}}\))\(^2\)\(^-\) dianion is known to be the most appropriate way to formulate the formal charge distribution of this ligand,\(^{22}\) it should be noted that the phosphorus(v) centres withdraw...
electron charge from the nitrogen centres rendering them relatively soft donors more in keeping with the imino character that is drawn in Lewis-style depictions. Although the phosphorus(v) centres do polarise some of the methanediide charge, it is evident from extensive studies of early metal BIPMTMS chemistry that the majority of the dianion charge remains at carbon available for donation to a coordinated metal.  

Indeed, the experimental $^{13}$C NMR chemical shift of the methanediide ligands in 2Y is consistent with charge accumulation at these carbon centres and by inference this should be the case for 2Dy also. Thus, and in accord with experimental observations, the symmetrical disposition of the four nitrogen donors, which reside away from the formal equatorial plane due to the bite angle of the BIPMTMS ligand, imposes an axially symmetric equatorial potential (approximate $S_4$ symmetry) which reduces the strength of, but does not destroy, the axial potential of the C=Dy=C motif in 2Dy. It is germane to note that although the dysprosium centre in 2Dy is of pseudo-octahedral geometry, an effectively linear charge build-up is obviously felt by the dysprosium centre, resulting in strong axial anisotropy, as evidenced by the magnetic behaviour of this system. If the pincer nitrogen donors could be replaced by more weakly coordinating groups, the $U_{\text{eff}}$ value(s) would be even higher, providing obvious targets for subsequent studies.

For 1Dy the ground doublet is largely $|\pm 11/2\rangle$ with a small admixture of $|\pm 1/2\rangle$, while the second doublet is more significantly mixed but still shows a dominant 81% $|\pm 13/2\rangle$ contribution (see Table S4†). The compound has lower symmetry [$C=(\text{Dy=C(H)}=158.3^\circ]$ and has a weaker axial potential due to the mono- and di-anionic ligands vs. the bis(di-anionic) set of 2Dy. The result is that the third doublet has a main magnetic axis perpendicular to the ground state and shows significant transverse $g$-factors, thus providing an efficient thermal relaxation pathway. Fig. S13 and Tables S5 and S6†. The calculated $U_{\text{eff}}$ value of 245 K agrees very well with the experimentally determined value of $U_{\text{eff}} = 255$ K.

**Lucinescence studies**

To further test and corroborate the validity of our model, variable temperature optical emission spectroscopy has been performed for 2Dy; we report results recorded at 13 K. After excitation with UV irradiation, sensitised complexes of DyIII are known to exhibit luminescence in the optical region owing to radiative decay from the $^4F_{9/2}$ multiplet to the $^6H_j$ multiplets, with photon energies (wavelengths) of approximately 21 100 cm$^{-1}$ (475 nm), 17 500 cm$^{-1}$ (570 nm) and 15 200 cm$^{-1}$ (660 nm), for the $j = 15/2, 13/2$ and 11/2 multiplets, respectively. After excitation at 375 nm, 2Dy exhibits strong emission at 20 000–21 000 cm$^{-1}$ ($j = 15/2$) and 16 700–17 700 cm$^{-1}$ ($j = 13/2$) but only weak signals are observed around 15 000 cm$^{-1}$ ($j = 11/2$), Fig. 6.

As it is possible to observe emission from excited crystal field doublets of the $^4F_{9/2}$ term, the only reliable transition is that of lowest energy into each multiplet, corresponding to a transition from the lowest lying $^4F_{9/2}$ state into the highest energy states of the $^6H_j$ multiplets. Therefore, using the low energy edge of the emission band to fix the location of the highest energy Kramers doublet in both the $^6H_{15/2}$ and $^6H_{13/2}$ multiplets, we compare the observed transitions to the calculated energy levels (Fig. 6). The most intense emissive feature in the $^6H_{15/2}$ multiplet ($\sim 20 500$ cm$^{-1}$) corresponds well to the calculated position of the third excited state, which suggests that the strong mixing of this state results in an enhanced transition probability. Conversely, transitions into the first excited and ground states of the $^6H_{15/2}$
The third doublet in $^1\text{Dy}$ and fourth and fifth doublets in $^2\text{Dy}$. This behaviour matches our predictions that a strong axial LF should give rise to a large $U_{\text{eff}}$ in lanthanide SMMS, accompanied by increased $T_B$ values. Compound $^1\text{Dy}$ is an excellent SMM in its own right, and shows very similar behaviour to those seen previously. In particular, quantum tunnelling of magnetisation (QTM) within the ground doublet is clearly important. This is seen by the very small hysteresis loop, but more decisively by the temperature independent relaxation rate below 10 K. The unique electronic structure of $^2\text{Dy}$ is responsible for generating a remarkably high $U_{\text{eff}}$ value, and leads to non-equilibrium behaviour below 16 K, where the details of the relaxation dynamics remains to be fully understood.

The AC data are unequivocal that relaxation between 20 and 40 K occurs by Orbach and Raman mechanisms alone; the Orbach process going via the fourth and fifth states at 721 and 813 K, respectively, which has been experimentally verified here for the first time. These are the largest $U_{\text{eff}}$ barriers reported for any monometallic dysprosium(m) complex to date, where a $U_{\text{eff}}$ of 481 K was previously the highest found in a Dy-salen-type Schiff base complex, but fall below 842 K for polymeric Dy@[$\text{Y}_4\text{K}_2\text{O}(\text{O}^\bullet\text{Bu})_2]_6$, and 938 K for a [Ta(Pc)_2] derivative. While Rajaraman and co-workers suggested that the slow magnetic relaxation of $[^{\text{Er}}\text{N(SiMe}_3\text{)}_3]_2$ could proceed by the fifth state, the experimental $U_{\text{eff}} = 122$ K seems much more compatible with relaxation via the second state at a spectroscopically-determined 158 K.

Below 16 K there are features we do not presently understand for $^2\text{Dy}$. Firstly, there is a large step at zero-field in $M(H)$ plots, which is conventionally explained as the hallmark of QTM. Our calculations predict a virtually pure $|\pm 15/2\rangle$ ground state and for such a state QTM should have a vanishingly small probability, therefore more work is required to investigate the relaxation mechanisms which cause this phenomenon. This step remains in the 3% diluted sample, and therefore it is possible that this is not dilute enough to completely remove transverse dipolar fields from nearby paramagnetic complexes. An alternative explanation is that nuclear hyperfine interactions may be responsible for this fast relaxation — a mechanism not accounted for in our purely electronic calculations. Such arguments have been made in Ho-SMMs, and have been studied recently by Pointillart et al., who show that isotopic enrichment with nuclear-spin-free $^{164}\text{Dy}$ provides a significant opening of the hysteresis loop compared to the $I = 5/2$ $^{164}\text{Dy}$ isotope. Synthesis and study of the isotopically enriched species is planned.

**Conclusions**

In the continued absence of true two-coordinate bis(alkylidene) lanthanide complexes, we have prepared complex $^2\text{Dy}$ which contains two methanediide centres that are disposed trans to one another. Although the pincer arms coordinate in off-axial positions, and in principle may carry some charge, it is clear that overall the dysprosium(m) bis(methanediide) complex $^2\text{Dy}$ possess a strong axial LF due to significant negative charge accumulation along the C=C axis. We find that the weak equatorial donors do not destroy this strong axial LF; this is in contrast to the recent report of Zhang et al. who show that erbium(m) complexes (which require strong equatorial LFs) are strongly affected by weak axial donors, lowering the $U_{\text{eff}} = 122$ K of [Er(N(SiMe_3)_3)_3] to $U_{\text{eff}} = 34$ K for [Er(N(H)Dipp)_3(THF)_3].

AC magnetic measurements of $^2\text{Dy}$ in zero DC field show temperature- and frequency-dependent SMM behaviour. Orbach relaxation dominates at high temperature, but a second-order Raman process becomes important as the temperature is lowered. We find thermal energy barriers ($U_{\text{eff}}$) of 721 and 813 K for two distinct processes, the largest $U_{\text{eff}}$ values reported for any monometallic dysprosium(m) complex. Ab initio calculations, which independently model the magnetic data remarkably well and are in good agreement with experimental optical spectra, suggest that the bottom three Kramers doublets of the ground $^6\text{H}_{15/2}$ multiplet of $^2\text{Dy}$ are essentially pure, well-isolated $|\pm 15/2\rangle$, $|\pm 13/2\rangle$ and $|\pm 11/2\rangle$ states quantised along the C=C axis. Thermal relaxation via the second and third states is quenched, and relaxation occurs via the fourth and fifth states because they are strongly mixed, with calculated $U_{\text{eff}}$ values of 742 and 810 K that compare very well to experimental values.

Magnetic measurements of $^2\text{Dy}$ suggest that $T_B = 10–12$ K, yet the FC/ZFC data show a clear divergence at $T_{\text{IRREV}} = 16$ K. Compound $^2\text{Dy}$ is therefore a peculiar molecule where the magnetism is history dependent at a temperature significantly above the conventional “blocking” temperature. Previous in-depth studies to assess the competing relaxation mechanisms have provided valuable insight into SMMs with conventional coordination numbers and geometries, and hence less extreme electronic structures. Compounds such as $^2\text{Dy}$ move us into a new area where chemical control of molecular geometry generates new and intriguing electronic structures. Despite a mature understanding of the microscopic origins of magnetic relaxation in complexes of the 3d metals, it is...
clear that more experimental and theoretical work is required to come to understand magnetic relaxation in 4f complexes and determine how chemistry may play a role in its control.\textsuperscript{28}

Given the properties of the molecules presented herein, realised by following a simple design strategy, we anticipate that such motifs could be employed with other contemporary Ln chemistry, using the idea of ‘building-block engineering’.\textsuperscript{29} For example, the recent report of a near-linear Dy–F–Dy linkage by Murugesu and co-workers\textsuperscript{28} suggests a tantalising molecular design with a linear C= Dy–F–Dy = C unit, which should provide a platform to examine in great detail the exchange interactions between pure m states.\textsuperscript{28} Alternatively, two collinear formal C= Dy = C units could be coupled through a radical ligand bridge which also represents a promising direction for Ln SMMs.\textsuperscript{22}

**Experimental section**

**General considerations**

All manipulations were carried out using Schlenk techniques, or an MBraun UniLab glovebox, under an atmosphere of dry nitrogen. Solvents were dried by passage through activated alumina towers and degassed before use or were distilled from calcium hydride. All solvents were stored over potassium hydroxide pellets and degassed by three freeze–thaw cycles and stored under a dry nitrogen atmosphere for extended periods as moisture-sensitive, but with adequate precautions they can be handled under a dry nitrogen atmosphere for extended periods with no sign of decomposition.

**Preparation of [Dy(BIPMTMS)(BIPMTMSH)] (1Dy).** BIPMTMS\textsubscript{2} (5.58 g, 10 mmol) in toluene (10 ml) was added dropwise to a precooled (−78°C) suspension of [Y(CH\textsubscript{2}Ph\textsubscript{3})(THF)\textsubscript{3}] (2.89 g, 5 mmol) in toluene (15 ml). The resulting orange suspension was warmed to room temperature with stirring over 16 h then refluxed for 10 minutes to afford a yellow solution. Volatiles were removed \textit{in vacuo} and the resulting yellow residue recrystallised from hot toluene (4 ml) to afford colourless crystals of 1Dy on cooling to room temperature. Yield: 2.02 g, 63%. Anal. calcd for C\textsubscript{82}H\textsubscript{116}DyKN\textsubscript{4}O\textsubscript{8}P\textsubscript{4}Si\textsubscript{4}: C, 58.33; H, 6.08; N, 4.39%. Found: C, 58.38; H, 6.05; N, 4.36%. FTIR ν/cm\textsuperscript{-1} (Nujol): 1306 (w), 1106 (m), 1047 (w), 841 (m, br), 697 (w), 610 (w), 553 (w), 522 (w). Magnetic moment (Evans method, C\textsubscript{6}D\textsubscript{6}, 298 K): \(\mu_{\text{eff}} = 10.61 \mu\text{B}\).

**Preparation of [Y(BIPMTMS)(BIPMTMSH)] (1Y).** BIPMTMS\textsubscript{2} (5.58 g, 10 mmol) in toluene (10 ml) was added dropwise to a precooled (−78°C) suspension of [Y(CH\textsubscript{2}Ph\textsubscript{3})(THF)\textsubscript{3}] (2.89 g, 5 mmol) in toluene (15 ml). The resulting orange suspension was warmed to room temperature with stirring over 16 h then refluxed for 10 minutes to afford a yellow solution. Volatiles were removed \textit{in vacuo} and the resulting yellow residue recrystallised from hot toluene (4 ml) to afford colourless crystals of 1Y on cooling to room temperature. Yield: 2.91 g, 48%. Anal. calcd for C\textsubscript{82}H\textsubscript{116}DyKN\textsubscript{4}O\textsubscript{8}P\textsubscript{4}Si\textsubscript{4}: C, 58.33; H, 6.08; N, 4.39%. Found: C, 58.74; H, 6.45; N, 4.57%. \textsuperscript{1}H NMR (C\textsubscript{6}D\textsubscript{6}, 298 K): 0.31 (18H, s, NSi(CH\textsubscript{3})\textsubscript{3}), 0.39 (18H, s, NSi(CH\textsubscript{3})\textsubscript{3}), 2.40 (1H, t, \(J_{PH} = 5.65 \text{ Hz}, \text{ C}(H)P\textsubscript{2}\)), 7.06 (12H, m, p-m-Ar-H), 7.25 (12H, m, p-m-Ar-H), 7.79 (8H, m, o-Ar-H), 7.94 (8H, m, o-Ar-H) ppm. \textsuperscript{13}C{\textsuperscript{1}H} NMR (C\textsubscript{6}D\textsubscript{6}, 298 K): δ 5.11 (NSi(CH\textsubscript{3})\textsubscript{3}), 6.16 (NSi(CH\textsubscript{3})\textsubscript{3}), 19.87 (1H, t, J\textsubscript{PC} = 45.24 Hz, i-Ar-C) ppm. \textsuperscript{31}P{\textsuperscript{1}H} NMR (C\textsubscript{6}D\textsubscript{6}, 298 K): δ 7.50 (d, J\textsubscript{FP} = 13.13 Hz, YC\textsubscript{H}(P)) ppm. 18C\textsubscript{6} (0.31 g, 1.17 mmol) in THF (2Dy).

**Preparation of [Dy(BIPMTMS)(BIPMTMSH)] (1Dy).** BIPMTMS\textsubscript{2} (4.47 g, 8 mmol) in toluene (10 ml) was added dropwise to a precooled (−78°C) suspension of [Dy(CH\textsubscript{2}Ph\textsubscript{3})(THF)\textsubscript{3}] (1.63 g, 2.5 mmol) in toluene (15 ml). The resulting orange suspension was warmed to room temperature with stirring over 16 h then refluxed for 10 minutes to afford a yellow solution. Volatiles were removed \textit{in vacuo} and the resulting yellow residue recrystallised from hot toluene (4 ml) to afford colourless crystals of 1Dy on cooling to room temperature. Yield: 2.02 g, 63%. Anal. calcd for C\textsubscript{82}H\textsubscript{116}DyKN\textsubscript{4}O\textsubscript{8}P\textsubscript{4}Si\textsubscript{4}: C, 58.33; H, 6.08; N, 4.39%. Luminescence. The sample was installed in a custom bored-out copper support and sealed with a sapphire window in a glove box environment before being transferred to the cold finger of a recycling He cryostat in which a vacuum of 10$^{-6}$ nbar or better was maintained. The sample temperature was monitored via silicon PIN diode and controlled using an Oxford Instruments ITC 503 Intelligent Temperature Controller. Photocreation was provided, off-axis by a 10 mW 375 nm coherent cube laser diode with an unfocussed spot size of 4 mm. The photoluminescence was collected using a collimating lens and focussed onto the slit of a 1 m, single 1200 lines mm$^{-1}$ grating spectrometer. The signal was detected using a Hamamatsu photon counting head and Stanford Research Systems SR400 gated photon counter from where it was read-in and displayed on a PC using a custom built LabView program.

Ab initio calculations. For all calculations the Dy atoms were treated with the ANO-RCC-VTZP basis, the N and C donors and the P atoms with the ANO-RCC-VDZP basis, while all other atoms were treated with the ANO-RCC-VDZ basis.43 The two electron integrals were Cholesky decomposed with the default thresholds. The 4$^f^9$ configuration of Dy$^{III}$ was modelled with a complete active space of 9 electrons in 7 orbitals, where 21 sextets, 210 octets, 130 doublents and 128 quartets are included in the orbital optimisation and 21 sextets, 128 quartets and 130 doublets were mixed by spin-orbit coupling. The ab initio results were then parameterised by a set of crystal field parameters,33 and then utilised to estimate the energy barriers to the reversal of magnetisation.44

Acknowledgements

We thank the Royal Society, EPSRC, ERC, COST, University of Nottingham and University of Manchester for generous funding and support. N. F. C. thanks The University of Manchester for a President’s Doctoral Scholarship and Prof. Hans U. Güdel for helpful conversations. I. F. C thanks Mr Eric Whittaker for engineering a novel sample mount and general assistance with the luminescence measurements.

This work is dedicated to and in memory of Prof. Malcolm Chisholm, with thanks for much friendly advice and encouragement.
