Polysulfide-1-oxides react with peroxyl radicals as quickly as hindered phenolic antioxidants and do so by a surprising concerted homolytic substitution†

Jean-Philippe R. Chauvin, Evan A. Haidasz, Markus Griesser and Derek A. Pratt*

Polysulfides are important additives to a wide variety of industrial and consumer products and figure prominently in the chemistry and biology of garlic and related medicinal plants. Although their antioxidant activity in biological contexts has received only recent attention, they have long been ascribed ‘secondary antioxidant’ activity in the chemical industry, where they are believed to react with the hydroperoxide products of autoxidation to slow the auto-initiation of new autoxidative chain reactions. Herein we demonstrate that the initial products of trisulfide oxidation, trisulfide-1-oxides, are surprisingly reactive ‘primary antioxidants’, which slow autoxidation by trapping chain-carrying peroxyl radicals. In fact, they do so with rate constants (k = 1–2 × 10^4 M⁻¹ s⁻¹ at 37 °C) that are indistinguishable from those of the most common primary antioxidants, i.e. hindered phenols, such as BHT. Experimental and computational studies demonstrate that the reaction occurs by a concerted bimolecular homolytic substitution (S₅₋₉), liberating a perthiyl radical – which is ca. 16 kcal mol⁻¹ more stable than a peroxyl radical. Interestingly, the (electrophilic) peroxyl radical nominally reacts as a nucleophile – attacking the α₁₋₅ of the trisulfide-1-oxide – a role hitherto suspected only for its reactions at metal atoms. The analogous reactions of trisulfides are readily reversible and not kinetically competent to inhibit hydrocarbon autoxidation, consistent with the longstanding view that organosulfur compounds must be oxidized to afford significant antioxidant activity. The reactivity of trisulfides and their oxides are contrasted with what is known of their shorter cousins and predictions are made and tested with regards to the reactivity of higher polysulfides and their 1-oxides – the insights from which may be exploited in the design of future antioxidants.

The antioxidant mechanisms of organosulfur compounds are often presented as complex. However, it is generally acknowledged that they must first be oxidized to render them effective. Organosulfur compounds are ascribed ‘secondary antioxidant’ activity since it is believed that they slow the rate of initiation (eqn (1)) by decomposing hydroperoxides. Two mechanisms are particularly important in this context: the direct reduction of hydroperoxides (eqn (5)) and the production of Bronsted or Lewis acids, which catalytically decompose hydroperoxides (eqn (6)) (Scheme 2).

Introduction

Organosulfur compounds have long been recognized to slow hydrocarbon autoxidation, the deleterious free radical chain reaction depicted in Scheme 1.† In fact, it was the pioneering work of Denison and Condit² in the 1940s that lead to the conclusion that “the oxidation stability of refined petroleum lubricating oils is the result of small quantities of natural sulfur compounds and not of any inherent stability of the hydrocarbon fraction itself. In the absence of the natural sulfur compounds the hydrocarbon fraction oxidizes rapidly and, in the initial stages of the reaction, autocatalytically”. Hence, although naturally-occurring organosulfur compounds are removed from crude oil in its refinement, organosulfur compounds comprise important additives to finished products.³
Secondary antioxidants can be contrasted with ‘primary antioxidants’, which inhibit autoxidation directly via reaction with chain-propagating peroxyl radicals. The most common examples of primary antioxidants - generally referred to as radical-trapping antioxidants (RTAs) - are phenols and diarylamines.

Organosulfur compounds may also act as primary antioxidants. Koelwijn and Berger showed that sulfides, upon oxidation to sulfoxides, undergo Cope-type elimination to yield a sulfenic acid (eqn (7)), which they surmised would undergo fast reactions with peroxyl radicals (eqn (8)). Since sulfenic acids are transient species that rapidly undergo self-reaction to yield thiosulfinate, they were unable to directly determine the kinetics of reaction (8), but estimated a rate constant of ca. $10^7$ M$^{-1}$ s$^{-1}$ based on inhibited autoxidations of tetralin with in situ formation of $t$-BuSOH from thermolysis of di-$t$-butyl sulfoxide at 60 °C.

Using a persistent sulfenic acid, 9-triptycenesulfenic acid, we recently determined the kinetics and thermodynamics of the reaction of a sulfenic acid with peroxyl radicals directly. The weak O–H bond in the sulfenic acid (71.9 kcal mol$^{-1}$) gives way to highly favourable reaction thermodynamics with peroxyl radicals (ca. 14 kcal mol$^{-1}$), and the presence of the sulfur atom π to the reactive O–H drives a very fast proton-coupled electron transfer reaction with peroxyl radicals ($k = 3 \times 10^9$ M$^{-1}$ s$^{-1}$) - despite the steric demand of the triptycenyli moiety.

Our studies of the radical chemistry of sulfenic acids were motivated by the widely reported antioxidant activity of allicin, the odorous thiosulfinate found in garlic, and petivericin, the analogous thiosulfinate from the medicinal plant Petiveria alliacea. We demonstrated that the antioxidant activity of both thiosulfinates was dependent on the Cope-type elimination of a sulfenic acid, which proceeds readily for both compounds at ambient temperature owing to the activated β C–H bond.

Since trisulfides and their oxides are among the most prevalent organosulfur compounds in Allium species (e.g., diallyltrisulfide and diallyltrisulfide-1-oxide from garlic) and are predominant among the mixtures of sulfurized materials added to protect petroleum-derived products from autooxidation, we wondered if they would possess ‘primary antioxidant’ reactivity analogous to that of hindered sulfoxides and activated thiosulfinates. Herein we report an investigation of the RTA activities of some trisulfides and their 1-oxides in an attempt to extend the foregoing knowledge to a more comprehensive view of the primary antioxidant activity of polysulfides and their 1-oxides, in general.

## Results

Given both the volatility and lability of diallyl trisulfide and its 1-oxide, their benzyl analogs, dibenzyl trisulfide (BnSSSBn) and dibenzyltrisulfide-1-oxide (BnS(O)SSBn), were investigated. These compounds, synthesized as described by Harpp and Stensaas, respectively, are solids at ambient temperature and allow direct comparison with petivericin (BnS(O)SBn) and its corresponding disulfide (BnSSBn). The reactivity of di-$t$-butyltrisulfide ($t$-BuSSSBn) and its 1-oxide ($t$-BuS(O)SSt-Bu) – also synthesized as described by Harpp – were also explored. These derivatives lack the activated β C–H in the allyl and benzyl moieties found in the garlic- and petiveria-derived allicin and petivericin, respectively.

### I. Inhibited autoxidations

The efficacies of the trisulfide-1-oxides as inhibitors of hydrocarbon autoxidation were investigated using styrene and cumene as model substrates. Although autoxidations are conventionally monitored by O$_2$ consumption, the recently developed method based on the competitive autoxidation of either PBD-BODIPY (with styrene) or STY-BODIPY (with cumene) was instead employed (Scheme 3). Representative
results are shown in Fig. 1A and B for varying amounts of BnS(O)SSBn and t-BuS(O)SS-t-Bu.

The data in Fig. 1A and B clearly demonstrate the ability of both trisulfide-1-oxides to retard the oxidation – and to a similar extent. From the rates of the retarded reactions, and assuming a stoichiometric factor of $n = 1$ (vide infra), the inhibition rate constants for BnS(O)SSBn and t-BuS(O)SS-t-Bu were calculated using eqn (11) to be $k_{inh} = (1.5 \pm 0.4) \times 10^8 \, \text{M}^{-1} \, \text{s}^{-1}$ and $(1.1 \pm 0.3) \times 10^4 \, \text{M}^{-1} \, \text{s}^{-1}$, respectively. The corresponding disulfides and trisulfides had no effect on the rate of PBD-BODIPY oxidation.

$$-\frac{d[\text{PBD-BODIPY}]}{dt} = \frac{k_p [\text{PBD-BODIPY}] R_i}{n k_{inh} [\text{antioxidant}]}$$

The lack of clear inhibited periods for the trisulfide-1-oxides in the foregoing styrene autoxidations precluded a determination of the stoichiometry for their reaction with peroxyl radicals. Therefore, co-autoxidations of cumene and STY-BODIPY were also carried out. These less oxidizable substrates generally provide greater resolution between inhibited and uninhibited phases of the autoxidation. The results are shown for t-BuS(O)SS-t-Bu and BnS(O)SSBn in Fig. 1C and D, respectively.

The STY-BODIPY/cumene co-autoxidations were less well inhibited by the trisulfide-1-oxides compared to the PBD-BODIPY/styrene co-autoxidations; in fact, t-BuS(O)SS-t-Bu was unable to inhibit the autoxidation at all, displaying instead a slight, but reproducible, acceleration of the autoxidation. This was particularly surprising given the greater propagation rate constants of Scheme 3

The absorbance of STY-BODIPY and PBD-BODIPY decrease as they are co-autoxidized with cumene and styrene, respectively. STY-BODIPY: $n = 1$, $\lambda_{max} = 591 \, \text{nm}$, $k = 141 \, \text{M}^{-1} \, \text{s}^{-1}$; PBD-BODIPY: $n = 2$, $\lambda_{max} = 571 \, \text{nm}$, $k = 2720 \, \text{M}^{-1} \, \text{s}^{-1}$.

Fig. 1 Thermally-initiated (AIBN, 6 mM) co-autoxidation of styrene (4.4 M) and PBD-BODIPY (10 μM) at 37 °C in chlorobenzene in the presence of either BnS(O)SSBn (A) or t-BuS(O)SS-t-Bu (B). Corresponding data is shown alongside for the AIBN-initiated (40 mM) co-autoxidation of cumene (3.6 M) and STY-BODIPY (10 μM) in the presence of BnS(O)SSBn (C) or t-BuS(O)SS-t-Bu (D).
PBD-BODIPY (2720 M$^{-1}$ s$^{-1}$) and styrene (41 M$^{-1}$ s$^{-1}$) compared to STY-BODIPY (141 M$^{-1}$ s$^{-1}$) and cumene (0.34 M$^{-1}$ s$^{-1}$). Kinetic analysis of the initial rates of the BnS(O)SSBn-inhibited autoxidations (i.e. eqn (11)) afforded $k_{inh} = (2.4 \pm 0.6) \times 10^4$ M$^{-1}$ s$^{-1}$; ca. 6-fold smaller than the rate constant derived from the styrene co-autoxidations. Nevertheless, the presence of a distinct inhibited period followed by reaction progress at the same rate as in the uninhibited reaction enabled the determination of the stoichiometry from the length of the inhibited period, $\tau$ (as in eqn (12)). The result was $n = 0.9 \pm 0.2$, thereby validating the assumption made in the styrene autoxidations (vide supra).

$$\tau = \frac{n[\text{antioxidant}]}{R_0} \quad (12)$$

To probe whether the benzylic H-atoms in BnS(O)SSBn play a role in its radical-trapping antioxidant activity, $d_4^{s}$BnS(O)SSBn was synthesized in a manner similar to that used to prepare $d_4^{s}$BnS(O)SBr in our previous work (see Experimental section), and its RTA activity was evaluated in styrene/PBD-BODIPY co-autoxidations. Experiments were also carried out wherein a small volume of a protic/deuteric solvent was added to co-autoxidations. Experiments were also carried out wherein a small volume of a protic/deuteric solvent was added to the trisulfide-1-oxide and methylperoxyl radical (R and R', respectively) were methyl groups. Despite extensive effort, a minimum energy structure for the intermediate in the step-wise reaction (eqn (13)) could not be located. However, transition states for both concerted homolytic substitutions were readily located, and are shown in Fig. 2A. The structures are 15.1 and 18.5 kcal mol$^{-1}$, respectively, higher in free energy than the separated reactants. Application of transition state theory affords rate constants of $3.8 \times 10^4$ and $14 \times 10^4$ M$^{-1}$ s$^{-1}$, respectively – the former in good agreement with the experimental data for BnS(O)SSBn of $(1.5 \pm 0.4) \times 10^4$. Replacement of the methyl substituents on the trisulfide-1-oxide and methylperoxyl radical with $t$-butyl groups increases the barrier by 3.7 kcal mol$^{-1}$ – consistent with the fact that $t$-BuS(O)SSBn-Br does not inhibit cumene autoxidation.

Both substitutions are predicted to be thermodynamically favourable: $\Delta G^0 = -9.3$ kcal mol$^{-1}$ for reaction at S1 (the sulfanyl sulfur) and $\Delta G^0 = -7.1$ kcal mol$^{-1}$ for reaction at S2. Much of the energetic benefit derives from exchange of the peroxyl radical for either of the more stabilized perthyl or sulfanyl radicals – which is clear when one considers the X–H BDEs (calculated by CBS-Q3) in MeSS–H (70.8 kcal mol$^{-1}$) and MeSO–H (68.4 kcal mol$^{-1}$) compared to MeOO–H (86.2 kcal mol$^{-1}$) – as well as the stronger S–O bonds in the products (40.1 and 37.2 kcal mol$^{-1}$ in MeOOS(O)Me and MeOOSSMe compared to 30.6 kcal mol$^{-1}$ for the S1–S2 bond in MeOSSMe). In the reaction at S1, the sulfanyl S–O bond length (1.480 Å) contracts ever so slightly from the starting material (1.487 Å), whereas in the reaction at S2, the sulfanyl S–O lengthens slightly (1.496 Å) on its way to becoming a free sulfanyl radical (1.511 Å). Consideration of the transition state structure suggests that the

Scheme 4 Mechanistic possibilities for the reaction of trisulfide-1-oxides with peroxyl radicals.
lone pair on the S1 sulfur does not participate directly in the reaction. In fact, the electronic structure of the transition state can essentially be viewed as interacting peroxyl, sulfinyl and perthiyl radicals (Fig. 3).

This view is reinforced by the results of natural bond orbital (NBO) analyses\(^1\) of the corresponding wavefunction, which is dominated by peroxyl \(\sigma^*\) (SOMO) \(\rightarrow \sigma_{\text{S1-S2}}\) and perthiyl \(\pi^*\) (SOMO) \(\rightarrow \sigma_{\text{S1-O}}\) interactions – worth a total of 73.5 kcal mol\(^{-1}\). Interestingly, the NBO analyses also reveal strong interactions between the lone pairs on the sulfinyl oxygen and the \(\sigma_{\text{S-S}}\) and \(\sigma_{\text{S1-O}}\) orbitals – worth a total of 60.2 kcal mol\(^{-1}\) – consistent with the fact that the transition state is stabilized by oxidation of S1.

For comparison, the analogous transition states for the reaction of a peroxyl radical with a thiosulfinate, transition state structures were again readily located for the reaction of the peroxyl radical with a thiosulfinate, and are shown in Fig. 2C. These structures are 13.8 and 17.6 kcal mol\(^{-1}\), respectively, higher in energy than the separated reactants. Interestingly, the barrier for reaction at S1 is even lower than that determined for the reaction of peroxyl radicals with the trisulfide-1-oxide. However, this reaction is endergonic by 3.0 kcal mol\(^{-1}\) – implying that it is readily reversible – while the reaction of the trisulfide-1-oxide is exergonic by 9.3 kcal mol\(^{-1}\). This difference arises largely since the reaction of the thiosulfinate produces a thyl radical, which is far less stable than the perthiyl radical (by 16.3 kcal mol\(^{-1}\), \(\text{vide supra}\)). Although the reaction of the thiosulfinate at S2 is significantly exergonic (\(\Delta G^0 = -8.1\) kcal mol\(^{-1}\)), it has a higher barrier. The rate constant calculated for substitution at S2 is 61 M\(^{-1}\) s\(^{-1}\), in reasonable agreement with rate constants determined experimentally for unactivated thiosulfinates (e.g. \(n\)-propyl \(n\)-propanethiosulfinate, for which \(k_{\text{inh}} = (244 \pm 31)\) M\(^{-1}\) s\(^{-1}\)).

III. Peroxyl radical-trapping by hydrosulfides

The foregoing computational results imply that the preferred reaction path between trisulfide-1-oxide and peroxyl radical yields a perthiyl radical. The stoichiometry observed in the inhibited autoxidations (\(n = 1\), \(\text{vide supra}\)) indicates that the perthiyl radical is unreactive under the autoxidation conditions. To confirm this point, benzyl hydrosulfide (BnSSH) was synthesized\(^2\) and its radical-trapping antioxidant activity investigated using the same STY-BODIPY/cumene co-autoxidation as for BnS(O)SBn (cf. Fig. 1C). The results are shown in Fig. 4.

The stoichiometry of the reaction of BnSSH with peroxyl radicals was determined to be \(n = 1.0 \pm 0.2\) from this data, consistent with a mechanism involving initial H-atom transfer...
from the hydropersulfide to a chain-carrying peroxyl radical and then no involvement of the resultant perthiyl radical in the reaction. It should be noted that hydropersulfides are evidently very potent radical-trapping antioxidants – similar in reactivity to α-tocopherol, Nature’s premier lipid-soluble radical-trapping antioxidant\(^ {33,34}\) – a result we will follow up on in subsequent work.

**IV. Direct measurements of the fate of perthiyl radicals**

The reaction of perthiyl radicals with \( \text{O}_2 \) has been reported in aqueous solution to occur with \( k = 5.1 \times 10^9 \text{ M}^{-1} \text{s}^{-1} \).\(^ {35}\) We initially expected that the resulting \( \text{RSSOO}^- \) may participate in the ensuing radical chemistry in the autoxidations inhibited by the trisulfide-1-oxide (and hydopersulfide). However, the foregoing results imply that \( \text{RSSOO}^- \), if formed, does not participate. It may also be that this radical is either not formed under the reaction conditions or that the reaction is readily reversible.

To provide insight on these possibilities, the reactivity of perthiyl radicals towards oxygen was investigated in chlorobenzene by laser flash photolysis. Di-tert-butyl tetrasulfide was used as a model compound, since it is known to yield a pair of perthiyl radicals upon UV irradiation.\(^ {36}\)

![](Image)

Photolysis of the tetrasulfide at 308 nm yielded a transient species with a pronounced absorption at 375 nm corresponding to the perthiyl radical (Fig. 5A). This transient absorption decayed rapidly (Fig. 5B) with concomitant reformation of the tetrasulfide at 340 nm (Fig. 5A).

The second order rate constant for the recombination of perthiyl radicals to the tetrasulfide was determined to be \( (6.0 \pm 0.5) \times 10^9 \text{ M}^{-1} \text{s}^{-1} \) at 25 °C (assuming \( \varepsilon_{300 \text{ nm}} = 1600 \text{ M}^{-1} \text{ cm}^{-1} \) based on pulse radiolysis studies of similar compounds\(^ {35,37,38}\)). This is ca. 4-fold larger than the reported values in water (1.5 and 1.9 \( \times 10^8 \text{ M}^{-1} \text{s}^{-1} \), respectively). Importantly, as is clear in Fig. 5B, no difference in the decay kinetics of the perthiyl radical could be detected in the presence or absence of \( \text{O}_2 \).

We also carried out a series of computations to probe the plausibility of the reaction of a perthiyl radical with \( \text{O}_2 \) (eqn (17)). It was not possible to find a bound perthiyl-\( \text{O}_2 \) adduct using the CBS-QB3 approach that we employed above (where geometries are obtained at the B3LYP/CBSB7 level of theory). However, when the calculations were carried out with basis sets that included diffuse functions on the heavy atoms, bond structures were located. The corresponding CBS-QB3(\( \delta^3 \)) \( \Delta G^0 \) was 12.9 kcal mol\(^{-1} \) with an associated barrier of \( \Delta G^\ddagger = 14.2 \) kcal mol\(^{-1} \) – consistent with the lack of reactivity determined experimentally.

![](Image)

**Discussion**

In line with the dogma that organosulfur compounds must be oxidized to afford antioxidant activity, trisulfides do not react at an appreciable rate with peroxyl radicals, while their 1-oxides are as reactive as hindered phenols, e.g., \( k_{\text{inh}} = 1.5 \times 10^9 \text{ M}^{-1} \text{s}^{-1} \) for \( \text{BnS(O)SSBn} \) and \( 1.4 \times 10^8 \text{ M}^{-1} \text{s}^{-1} \) for 2,6-di-tert-butyl-4-methylphenol (BHT).\(^ {40}\) Given the similar structure and reactivity of \( \text{BnS(O)SSBn} \) to petivericin, we initially wondered if it could undergo an analogous Cope-type elimination (eqn (18)) to
afford a good H-atom donor. This would account for both its need to be oxygenated and its relatively high $k_{\text{inh}}$ – which is too high for H-atom transfer from a benzylic C–H position ($\sim 1 \text{ M}^{-1} \text{s}^{-1}$).\(^{41}\)

While a transition state for this process was readily located in CBS-QB3 calculations on the corresponding allylic trisulfide-1-oxide (the benzyl groups were exchanged for allyl groups for computational expediency), the structure was a prohibitive 40.9 kcal mol\(^{-1}\) higher in energy than the starting material. For comparison, the transition state structure for Cope-type elimination of 2-propenesulfenic acid from allicin is calculated to have $\Delta H^\text{f} = 19.5$ kcal mol\(^{-1}\) (CBS-QB3), in good agreement with experimental observations.\(^{13,16}\)

Of course, the fact that t-BuS(O)SSt-Bu reacts with styrylperoxyl radicals with essentially the same rate constant as BnS(O)SSBn implies that the mechanism involves direct reaction at the trisulfide-1-oxide moiety. We initially surmised that this could take place by an addition/fragmentation mechanism, where the peroxyl radical would add to a lone pair on the sulfur atom to form an intermediate sulfur-centered radical that would be capto-datively stabilized by the sulfur atom on one side and the sulfinyl group on the other (eqn (13)). Subsequent $\alpha$-cleavage would yield either of two potential pairs of formal substitution products. However, computational efforts to provide evidence for this intermediate were unsuccessful.

Since computations indicated that the S(O)–SS bonds in trisulfide-1-oxides are weak (i.e. 29.8 kcal mol\(^{-1}\) in t-BuS(O)SSt-Bu by CBS-QB3 – see ES\(^{\dagger}\)), a concerted substitution was considered next. This seemed unlikely since it requires that the peroxy radical serve nominally as the nucleophile. Nevertheless, transition state structures were readily located for substitution at each of the sulfinyl sulfur atom (S1) and S2. Substitution at S1 was predicted to take place with a lower barrier (15.1 kcal mol\(^{-1}\) vs. 18.5 kcal mol\(^{-1}\) for substitution at S2) and the corresponding rate constant obtained from application of transition state theory was in good agreement with our experiments. This mechanism is also consistent with the lack of deuterium kinetic isotope effects on peroxy radical-trapping by either t-BuS(O)SSt-Bu ($k_{\text{H}}/k_{\text{D}} = 1.0$) or BnS(O)SSBn ($k_{\text{H}}/k_{\text{D}} = 1.4$). This is in sharp contrast with the large KIEs observed for petivericin ($k_{\text{H}}/k_{\text{D}} = 16$ or 18.2, depending on experimental approach) – whose mechanism involves two isotope-sensitive steps: C–H bond cleavage in the Cope-type elimination and O–H bond cleavage in the formal H-atom transfer from the sulfinic acid to the peroxy radical.\(^{43}\)

The rates of reactions of peroxy radicals with RTAs are generally independent of the structure of the peroxy radical; that is, inhibited autoxidations of styrene or cumene, where the chain reaction is carried by styrylperoxyl or cumylperoxyl radicals, respectively, usually yield the same inhibition rate constant.\(^{49}\) The fact that the trisulfide-1-oxides react at different rates with these peroxy radicals, and that the steric demand of the substituents on the trisulfide-1-oxide have a greater impact on the rate when the peroxy radical is also hindered (cumylperoxyl), further support that these reactions take place by a homolytic substitution mechanism at the sulfinyl sulfur atom.

Thus, the RTA activity of the trisulfide-1-oxides in organic solution can be ascribed to the reactions in Scheme 5. The substitution products are a perthyl radical and a peroxysulfinate ester (eqn (19)). Interestingly, in contrast with the literature precedent (in aqueous solution), our flash photolysis experiments indicate that the perthyl radical rapidly combines with another of itself to form a tetrasulfide (eqn (20)) even in the presence of O$_2$. The peroxysulfinate ester is the same product that is formed upon reaction of a sulfinyl radical with a peroxy radical, and is believed to rapidly rearrange to a sulfonate ester (eqn (21)) – possibly by O–O cleavage and in-cage recombination.\(^{13,16}\) This reaction mechanism is consistent with all of the foregoing data, including the fact that a trisulfide-1-oxide traps a single peroxy radical under ambient conditions, unlike activated thiosulfinates and sulfoxides, which trap 2.
It seems reasonable to suggest that the reactivity of trisulfide-1-oxides and tetrasulfide-1-oxides extends to higher polysulfide-1-oxides, since the S–S bond strength in higher polysulfides is essentially independent of the number of sulfur atoms.26 The generality of this reactivity is in sharp contrast to that of the lower thiosulfonates and sulfoxides, whose activities require appropriate substitution to promote Cope-type elimination of a sulfenic acid.

**Conclusions**

The RTA activity of trisulfides, tetrasulfides and their corresponding 1-oxides were determined by inhibited autoxidations. In each case, the polysulfides were inactive, while their 1-oxides were as reactive as hindered phenols – the most common type of primary antioxidant – with $k_{inh} \sim 1$ to $2 \times 10^4$ M$^{-1}$ s$^{-1}$. Kinetic isotope effects, steric effects and high level computations are consistent with a bimolecular homolytic substitution mechanism wherein the peroxyl radical is the nominal nucleophile, attacking the $\text{S}_n^-$ of the polysulfide-1-oxide. The stoichiometry of the reaction of the trisulfide-1-oxides with peroxyl radicals was determined to be $n \sim 1$, indicating that the peroxysulfinate ester initially formed rearranges to a sulfonate ester instead of cleaving to yield an alkoxyl radical that would propagate the chain. The other substitution product, the persulfenic radical, simply combines with another of itself to form a tetrasulfide. It is anticipated that higher polysulfide-1-oxides undergo the same rapid bimolecular homolytic substitution reactions with peroxyl radicals. This chemistry may contribute to the antioxidant activity of *Allium*-derived polysulfides, such as garlic’s diallyltrisulfide, as well as that of sulfurized olefins that are added as secondary antioxidants to petroleum-derived products. Results of further investigations along these lines will be reported in due course.

**Experimental section**

1. **General**

All chemicals and solvents were purchased from commercial suppliers and used without further purification unless otherwise indicated. PBD-BODIPY and STY-BODIPY were synthesized following our previously reported procedure.26 Styrene and cumene were extracted three times with NaOH (1 M), washed with water, dried with MgSO$_4$, filtered, distilled under reduced pressure and percolated through a silica column. They could be kept at −20 °C under nitrogen for up to 5 days. Immediately before use, the distilled material was percolated again through a silica/basic alumina (1 : 4) column. Chlorobenzene was dried over 3 Å molecular sieves before use. SC$_2$H$_2$ was distilled in the presence of PCl$_3$ and used within 2 hours. BnSSSBn, t-BuSSSBn and t-BuSSSSBn were prepared according to a previously reported procedure.23 Similarly, BnS(O)SBn, BnS(O)SSBn, t-BuS(O)SSBn, t-BuS(O)SSSSBn and t-BuS(O)SSSSSb were prepared according to previously reported procedures. UV-visible spectra were measured with a spectrophotometer equipped with a thermostatted 6 × 6 multi cell holder.
d₄-BnSSSBn. Potassium carbonate (2.35 g, 17.0 mmol) was added portion-wise to a stirred solution of d₂-BnSAC²³ (2.35 g, 14.0 mmol) in methanol (40.0 mL). After 1 hour, it was extracted with ether. The organic layer was then washed with water and brine, dried with MgSO₄, filtered and the solvent removed under reduced pressure to yield crude d₂-BnSH as a pale yellow oil (1.66 g, 94%), which was used without purification. Freshly distilled ScI₃ (411 mg, 4.00 mmol) was added to dry ether (20.0 mL) and cooled to −78 °C under argon. One equivalent of d₂-BnSH (504 mg, 4.00 mmol) and triethylamine (404 mg, 4.00 mmol) in ether (10.0 mL) were then added dropwise to the cooled ScI₃ solution over a period of 30 minutes. The solution was stirred for another 30 minutes after the addition was completed. A second equivalent of d₂-BnSH and triethylamine (404 mg, 4.00 mmol) in ether (10.0 mL) were then added dropwise to the cooled solution over a period of 30 minutes. The solution was stirred for another 30 minutes after the addition was completed. After completion of the reaction (as judged by TLC analysis), the reaction mixture was diluted with ether, washed with water, saturated aqueous NaHCO₃, water and brine. The organic layer was dried with MgSO₄, filtered and the solvent removed under reduced pressure. The crude dark orange oil was recrystallized from CH₂Cl₂ (2.00 mL) and cooled to 0 °C for approxi-mately 50 min. No crystals were formed, only a yellow oil. The crude dark orange oil (1.66 g, 84%), which was used without further purification, was washed with water, saturated aqueous NaHCO₃, water and brine. The organic layer was dried with MgSO₄, filtered and the solvent removed under reduced pressure. The crude white solid was recrystallized from hexanes and ether to afford the final product as white crystals (767 mg, 100%). ¹H NMR (400 MHz; CDCl₃): δ 7.38–7.27 (m, 10H). ¹³C NMR (100 MHz; acetone-d₆): δ 137.67, 130.31, 129.41, 128.35. HRMS ESI [M + Na]+: calculated for C₆H₄O₂S₂Na: 282.05087; found: 282.05220.

d₄-BnSO(S)SBn. A solution of m-CBPA (155 mg, 0.90 mmol) in CH₂Cl₂ (2.00 mL) was added dropwise to a solution of d₄-BnSSSBn (282 mg, 1.00 mmol) in CH₂Cl₂ (1.50 mL) at 0 °C. The solution was stirred at 0 °C for 20 minutes after which all the trisulfide was consumed (as judged by TLC). The reaction mixture was diluted with CH₂Cl₂ and washed with saturated aqueous NaHCO₃, water and brine. The organic layer was dried over MgSO₄ and removed under reduced pressure. The crude white solid was recrystallized from hexanes and ether to afford the final product as white crystals (229 mg, 77%). ¹H NMR (400 MHz; CDCl₃): δ 7.38–7.27 (m, 10H). ¹³C NMR (100 MHz; CDCl₃): δ 136.60, 130.45, 129.96, 129.23, 128.94, 128.84, 127.90. HRMS ESI [M + Na]+: calculated for C₄₄H₄ₒD₄O₄S₄Na: 321.03555, found: 321.03790.

II. Inhibited co-autodisolutions
The inhibited autodisolutions were carried out following our recently published procedure.²⁶ A 3.5 mL quartz cuvette was added styrene or cumene (1.25 mL) along with PhCl, such that the final reaction volume is 2.50 mL. The cuvette was then preheated in a thermostatted sample holder of a UV-vis spectrophotometer and allowed to equilibrate to 37 °C for approximately 15 minutes. A small volume (12.5 µL) of a 2.00 mM solution of the BODIPY probe in 1,2,4-trichlorobenzene was added, followed by the appropriate amount of 0.300 M solution of AIBN in PhCl to achieve the required rate of initiation (typically 50 µL, where R₁ = 2.2 × 10⁻⁹ M s⁻¹). The solution was thoroughly mixed. The absorbance at either 591 nm (PBD-BODIPY) or 571 nm (STY-BODIPY) was monitored for 30–45 min to ensure that the reaction was proceeding at a constant rate, after which 10.0 µL of a solution of the test antioxidant was added. The solution was thoroughly mixed and the absorbance readings resumed. The resulting data was processed as previously reported.²⁶ The rate of initiation (R₁ = 1.1 × 10⁻⁹ M s⁻¹) and k₂θ = 2.8 × 10⁻⁷ M⁻¹ s⁻¹ for 40 mM AIBN in cumene, necessary to derive stoichiometric data, was determined using PMC as a standard, which has an established stoichiometry of 2.⁴⁰

III. Laser flash photolysis
Nonasecond transient absorption experiments were performed on an LFP-112 spectrometer (Luzchem, Canada). Excitation was performed using an EX10 (GAM Laser, USA) XeCl Excimer laser (308 nm, ca. 10 mJ per pulse, ca. 12 ns pulse width). The transient absorption spectra were recorded in a quartz cuvette (1 cm × 1 cm) equipped with a septum and samples were bubbled with nitrogen or oxygen for 10 minutes before measurement.

IV. Calculations
Calculations were carried out using CBS-QB3 complete basis method as it is implemented in the Gaussian 09 suite of programs.²⁸ CBS-QB3(+) calculations were performed for the perthiyl-O₂ adduct, wherein the geometry of the adduct was optimized at the B3LYP/6-311+G(2d,d,p) level of theory and the resulting frequencies read into the CBS-QB3 calculation of Gaussian 09 without further modifications. Due to the large size of the structure, calculations for the transition states of the reactions of trisulfide-1-oxide and peroxy radicals with t-butyl substituents were carried out with only the first two steps of the CBS-QB3 calculation (B3LYP/CBSB7).

This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada and the Canada Foundation for Innovation. DAP acknowledges support from the University of Ottawa and the Canada Research Chairs program, respectively. JPRL and EAH acknowledge the support of Ontario Graduate Scholarships.

Notes and references
The inhibition rate constant could not be determined in styrene predominantly due to the addition of the perthiyl radical onto the styrene moiety. This is currently under further investigation.
