1. Introduction

Porous structures possessing weakly bound charge-balancing ions are essential for the development of new separation technologies and the removal of pollutant ions from aqueous environments. The capture of toxic perchlorate (ClO₄⁻) presents unique challenges due to its high solubility and non-complexing nature, making it highly mobile and resistant to traditional wastewater treatment technologies. Perchlorate is an emerging trace contaminant in groundwater and has gained significant attention, as it has become widespread in many countries. This anionic pollutant can block the uptake of iodide by the thyroid due to their equivalent charge and similar ionic radii. This blockage can disrupt the production of thyroid hormones and affect metabolism, possibly leading to hypothyroidism or mental retardation in fetuses and infants. Perchlorate salts are used as the conventional solid oxidant in the industrial manufacture of rocket fuel, explosives, flares and fireworks. Commercially available ion exchange resins are single use and exhibit limited thermal and chemical stability, while other ion exchanging materials such as layered double hydroxides (LDHs) display poor selectivity and adsorption capacity for perchlorate. Higher performing ion exchangers are therefore sought to reversibly capture perchlorate at greater capacity and selectivity. In particular, metal–organic frameworks (MOFs) have gained significant attention in the selective capture of pollutants via ion exchange.

Recently, MOFs have been under intense investigation due to their ability to exchange their intrapore or interlayer ions with other ionic species in solution. Their structural integrity is not compromised, which make these materials excellent candidates for the separation of pollutants. The adsorptive separation of pollutant species in the gas phase, such as carbon dioxide or methane, is driven by the reversible dynamic behavior of the network, often referred to as “breathing”. This action results in a change of interaction strength between the guest molecules and host framework due to framework displacement accompanied by a change in the unit cell volume. There has been much less effort into understanding the structural flexibility and dynamic transformations that solid MOFs exhibit during adsorption and/or ion exchange. The mechanism by which such ion exchange processes take place has been proposed to be either by a solid state or a solvent-mediated transformation. In the case of a solid state transition, the ion exchange proceeds through the diffusion of free ions within the channels of the coordination polymer crystals. In contrast, the solvent-mediated process involves the dissolution of the initial coordination polymer followed by the formation and crystallization of a new coordination polymer from the solution phase.

The structural transformations that coordination polymers undergo during ion exchange processes can be monitored by single crystal or powder X-ray diffraction (PXRD) of the MOF in combination with analytical measurements of the solution towards incoming and outgoing guests. If possible, single crystal X-ray crystallographic methods are preferred for the...
exact structural determination of the new MOF phase upon adsorption. This methodology, however, provides limited structural information regarding the dynamic behavior of the framework during exchange due to the absence or sufficient size/quality of crystals. In contrast, magic-angle spinning (MAS) nuclear magnetic resonance (NMR) spectroscopy provides structural information about the local environment of various nuclei in solids, including both the metal nodes and the organic linkers of the MOFs. Hence, NMR spectroscopy could be used in conjunction with XRD methods as a complementary technique for analyzing the exchange dynamics of MOF materials. NMR is well suited to probe the structural flexibility and reversible dynamic behavior of a framework undergoing ion exchange. Jiang et al. reported the structural flexibility of a Cu(bipy)$_2$(H$_2$O)$_2$(BF$_4$) (bipy = 4,4'-bipyridine) framework by chemisorption of probe molecules that could induce reversible structural changes. The transitions could be monitored by $^{11}$B MAS NMR as a result of the change in polarization of the probe molecule and its interaction with the Cu(II) paramagnetic sites.

In our previous work, we reported the successful capture of aqueous perchlorate by Silver 4,4'-Bipyridine Nitrate (SBN) to yield a Silver 4,4'-Bipyridine Perchlorate (SBP) MOF. We showed that SBN effectively exchanged guest NO$_3^-$ ions for ClO$_4^-$ ions at a record capacity of 354 mg g$^{-1}$ within 90 minutes. The material also selectively captured this pollutant in the presence of 50-fold molar SO$_4^{2-}$ and CO$_3^{2-}$, suggesting this methodology could be applied to treat perchlorate pollution at underground plume sites. In addition, SBN displayed excellent reusability: 96% of SBP could be regenerated back to SBN over multiple cycles while maintaining uptake capacity. Anion exchange by metal bipyridine and pyrazine coordination polymers was evaluated by Schröder and coworkers utilizing several anions such as BF$_4^-$ and PF$_6^-$.

The uptake was determined to be a solvent mediated process driven by the relative hydration energy of the anions residing in the pores. In our previous work, we reported the successful capture of aqueous perchlorate by Silver 4,4'-Bipyridine Nitrate (SBN) to yield a Silver 4,4'-Bipyridine Perchlorate (SBP) MOF. We showed that SBN effectively exchanged guest NO$_3^-$ ions for ClO$_4^-$ ions at a record capacity of 354 mg g$^{-1}$ within 90 minutes. The material also selectively captured this pollutant in the presence of 50-fold molar SO$_4^{2-}$ and CO$_3^{2-}$, suggesting this methodology could be applied to treat perchlorate pollution at underground plume sites. In addition, SBN displayed excellent reusability: 96% of SBP could be regenerated back to SBN over multiple cycles while maintaining uptake capacity. Anion exchange by metal bipyridine and pyrazine coordination polymers was evaluated by Schröder and coworkers utilizing several anions such as BF$_4^-$ and PF$_6^-$.

The uptake was determined to be a solvent mediated process driven by the relative hydration energy of the anions residing in the pores. Herein, we report a study of the host–guest interaction of an Ag-bipy coordinated polymer during NO$_3^-$ and ClO$_4^-$ anion exchange dynamics. The structural transformation is followed by analysis of the [Ag-bipy] material at different time intervals using PXRD to assess the presence of two structural phases corresponding to SBN and SBP. The structural transformation during exchange is further investigated by recording multinuclear $^{13}$C, $^{15}$N and $^{109}$Ag cross-polarization (CP) MAS NMR spectra. $^{13}$C [1.13% natural abundance (nat. ab.), nuclear spin $I = 1/2$] NMR is used to quantify the SBN to SBP ratio during the anion exchange. $^{15}$N (0.37% nat. ab., $I = 1/2$) NMR determines whether NO$_3^-$ is present and probes the bonding between the nitrogen of bipy and silver via the scalar $J$ coupling interaction and is further confirmed by $^{109}$Ag (48.18% nat. ab., $I = 1/2$) NMR. In addition, this exchange is further investigated by inspecting the morphological changes of the crystalline materials by scanning electron microscopy (SEM).

2. Experimental

2.1 Synthesis

In short, a mixture of AgNO$_3$ (AgNO$_3$, Fisher, 99%, 0.1 g, 0.59 mmol), 4,4'-bipyridine (Acros Organics, 98%, 0.1 g, 0.64 mmol) and deionized water (10 mL) was stirred at room temperature for 3 days in a sealed beaker. Pale gray crystals were isolated after filtration and rinsed with water (10 mL) and acetone (5 mL) to yield SBN (0.187 g, 97.6% based on silver nitrate). Batch anion exchange experiments were carried out under ambient conditions by mildly stirring the ground SBN (80 mg, 0.25 mmol) with 50 mL deionized water and NaClO$_3$ (Fluka Analytical, 98%, 35 mg, 0.25 mmol). The post-exchange crystalline SBP product was recovered at the different time intervals by vacuum filtration and rinsed with water (10 mL) and acetone (5 mL).

2.2 Regeneration

The regeneration of SBN from SBP was carried out by stirring the ground SBP (80 mg, 0.22 mmol) in a 0.1 M NaNO$_3$ solution (NaNO$_3$, Fisher, 99%) at 70 °C for 24 h. The regeneration of the SBN was studied by recording the PXRD, $^{13}$C, $^{15}$N, $^{109}$Ag CP MAS NMR data and SEM images after treatment of the SBP material with excess nitrate at 70 °C under stirring.

2.3 Characterization

PXRD data were measured on a Rigaku Americas Miniflex Plus diffractometer, scanning from 2 to 40° (2θ) at a rate of 2° min$^{-1}$ with a 0.04° step size under Cu Ka radiation ($\lambda = 1.5418$ Å). Ion Chromatography (IC) analysis was performed to assess the perchlorate concentration using a Dionex ICS-3000 with an IonPac AS20 column and a detection limit of 3 ppb. SEM data were collected with a FEI Quanta 3D Dualbeam microscope. Solid-state NMR experiments were performed at room temperature on a Wide Bore 400 MHz 9.4 T Bruker Avance III HD NMR spectrometer equipped with a 4 mm HXY triple-resonance MAS probe (in double resonance mode) for $^{13}$C and $^{15}$N and with a 4 mm HX MAS probe for $^{109}$Ag or on a Wide Bore 850 MHz 20 T Bruker Avance II NMR spectrometer equipped with a 3.2 mm HXY triple-resonance MAS probe (in double resonance mode) for $^{13}$C. Data acquisition was performed with cross polarization (CP) and SPINAL-64 heteronuclear decoupling. Recycle delays ranging from 30 to 180 s were used and correspond to 1.3 × $^1$H $T_1$ (measured by $^1$H saturation recovery experiments). All other experimental details are given in Table S1. The $^{13}$C, $^{15}$N and $^{109}$Ag chemical shifts were referenced to the CH carbon of adamantane at 29.45 ppm, $^{20}$g glycine at 33.4 ppm (corresponding to liquid NH$_3$ at 0 ppm) and a saturated solution of AgNO$_3$ in D$_2$O [with 0.24 M of Fe(NO$_3$)$_3$] at 0 ppm, respectively. All samples were packed in air. Using the Haeberlen convention, the principal components $\delta_{11}$, $\delta_{22}$, $\delta_{13}$ of the chemical shift tensors were defined such that $|\delta_{13} - \delta_{iso}| \geq |\delta_{11} - \delta_{iso}| \geq |\delta_{22} - \delta_{iso}|$ where $\delta_{iso}$ is the isotropic chemical shift and related to the principal components of the shielding tensor by $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{13})/3$. The chemical shift anisotropy $\delta_{aniso}$ is defined as

\[ \delta_{\text{aniso}} = \delta_{33} - \delta_{11} \] and the deviation from axial symmetry given by the asymmetry parameter \( \eta = (\delta_{22} - \delta_{11})/\delta_{\text{aniso}} \).

**3. Results and discussion**

The synthesis of SBN can be carried out at room temperature by the initial dissociation of silver nitrate followed by the self-assembly of the cationic polymer chains, charge balanced by nitrate ions. SBN can undergo quantitative anion exchange upon exposure to \( \text{ClO}_4^- \) in solution to yield SBP with a 99% conversion as determined by monitoring the concentration of \( \text{ClO}_4^- \) in solution from ion chromatography (IC). The PXRD data confirms the identity of the two crystalline phases as they match the theoretical patterns based on the single crystal solution (Fig. S1†).

Both SBN and SBP structures consist of Ag(i) chelated by the nitrogens of two different (\( \mu-2 \))-4,4'-bipyridine units that result in extended polymeric chains. The chains align parallel into a non \( \pi \)-stacked layer where the rings are coplanar with the plane of the page. The two structures differ in the arrangement of their subsequent layers. For SBN, the cationic layers are rotated by 90°, forming a cross-criss pattern in which half the pyridine rings \( \pi \)-stack in a staggered manner with a distance of 3.55 Å from the next layer (Fig. 1). In addition, half of the Ag(i) centers are dimerized and cross linked to the next layer by the formation of Ag–Ag bonds with a distance of 2.97(1) Å. In contrast, the cationic layers of SBP are eclipsed, resulting in \( \pi \)-stacking of all the pyridine rings and a shorter interlayer distance of 3.47 Å (Fig. 1). The Ag(i) centers have a long contact distance of 3.60(1) Å, which is well above the covalent range. These longer Ag–Ag distances allow for the spherical \( \text{ClO}_4^- \) anions to be more spread out between the polymeric interlayers. The \( \text{ClO}_4^- \) to Ag(i) distance is therefore greater for SBP than for SBN but closer contact of the anions to the bipyridine HCIV in SBP (Table 1).

Based on the above structural considerations, it is clear that the two coordination polymers are structurally different in the arrangement of the cationic layers as well as the location of the anions. Such structural differences suggest that the anion exchange may proceed by a solvent-mediated process involving the initial dissolution of the SBN T-shaped polymers followed by the crystallization of eclipsed SBP polymers from the perchlorate solution (Fig. S2†). In order to support this hypothesis, the anion exchange was monitored versus time by both PXRD (Fig. 2) and multinuclear MAS NMR (Fig. 3). After 10 minutes of exposure to \( \text{ClO}_4^- \), the intensity of the low angle (002) peak decreases and a new set of peaks [e.g. 22° (2\( \theta \)) corresponding to the (211) plane of the SBP crystalline phase] begin to appear, indicating initiation of the process.

After 25 minutes, the PXRD pattern is an approximately equal mixture of both the SBN and SBP crystal phases, indicating that the anions have been partially exchanged. The relative amounts of both phases were verified by measuring the residual concentration of perchlorate in the anion exchange solution at different time intervals with ion chromatography (Fig. S3†). The predominance of the SBP phase is observed after 40 minutes, where the low angle peaks corresponding to (001) and (100) of SBP are now higher intensity relative to the

![Fig. 1](Image) (a) Crystallographic view of SBN in the "a" plane and (c) "b" plane. (b) Crystallographic view of SBP in the "a" plane and (d) "c" plane. The nitrate oxygens are disordered between two sites (Ag, magenta; N, blue; O, red; C, black; Cl, green).

![Fig. 2](Image) PXRD patterns of the SBN/SBP anion exchange of SBN pre-exchange (black), after 10 min (red), 25 min (blue), 40 min (green), complete exchange to SBP after 70 min (purple), and regeneration to SBN (grey).
peaks of SBN. After 70 minutes, the anion exchange is complete and the PXRD pattern is pure phase SBP (see below for recovery to SBN). In addition, a shift in the (001) and (100) phases to a higher 2-theta indicates that the d-spacing decreased, likely due to a contraction of the structure upon completion of the anion exchange.

The $^{13}$C CP MAS NMR spectra of SBN and SBP (black and purple spectra, Fig. 3a) obtained at 20 T show three different isotropic resonances $\delta_{\text{iso}}$ at 153.3–152.7, 144.1–143.8 and 123.3–121.7 ppm for the individual carbons in the asymmetric unit and correspond to the CHN, C$^\text{IV}$ and CHC$^\text{IV}$ environments in the 4,4′-bipyridine ligand, respectively. As the NO$_3^-$–ClO$_4^-$ anion exchange progressed by dissolution of SBN and subsequent capture of the ClO$_4^-$ by the crystallization of SBP, a downfield shift of around 1.6 ppm is clearly observed in the signal of the CHC$^\text{IV}$ carbon (Fig. 3a, S4 and S5$^\dagger$).

Comparison of the CHC$^\text{IV}$ signal intensities at 121.7 and 123.3 ppm for SBN and SBP, respectively, enables a semi-quantitative analysis of the rates of exchanges to be monitored (note that while CP MAS NMR experiments are not quantitative, integration is performed on the same CHC$^\text{IV}$ carbon, therefore a SBN/SBP ratio could be approximately estimated). After 10 and 25 minutes, approximately 20 and 60% of SBN have been transformed into SBP, respectively. Partial degree of exchange at these time intervals agrees well with the PXRD data (red and blue patterns, Fig. 3).

This shift difference between the CHC$^\text{IV}$ carbon in SBN and SBP is probably due to the higher degree of carbon deshielding caused by the perchlorate anions. As stated above, the cationic layers of SBP have a shorter π-stacking distance relative to SBN due to the fully eclipsed arrangement of the Ag-bipy chains. This shorter distance causes the ClO$_4^-$ anions to be more tightly packed between the aromatic rings and in turn a longer Ag-O distance. Consequently, the ClO$_4^-$ oxygens are in closer proximity to CHC$^\text{IV}$ carbon, resulting in a higher degree of deshielding as reflected by the observed chemical shift.

The $^{15}$N CP MAS NMR spectrum of SBN (Fig. 3b, black) at 9.4 T reveals two isotropic resonances $\delta_{\text{iso}}$ at 379.3 and 263.9 ppm and are assigned to the NO$_3^-$ anions and the nitrogen of the bipy ligand, respectively. A doublet of 84 Hz is observed for the former resonance and results from the indirect scalar $J(15N, 107, 109\text{Ag})$ coupling arising from coordination of the nitrogen atoms of bipy to the silver atoms, as expected from the crystal structure (Fig. 1). Similar scalar coupling constants were obtained in a series of linear or almost linear two-coordinate [Ag(NH$_3$)$_2$]$^+$ ions.$^{24}$

The $^{109}$Ag CP MAS NMR$^{25}$ spectrum of SBN (purple, Fig. 3c) shows a series of intense spinning sidebands spanning over approximately 1000 ppm, in agreement with a large chemical shift anisotropy of $\delta_{\text{aniso}} = \sim 774$ ppm. Note that the relatively low signal to noise ratio of this $^{109}$Ag spectrum arises from the very low magnetic moments of this nucleus. A single isotropic resonance appears at $\delta_{\text{iso}} = 438.5$ ppm and is consistent with a single silver atom environment in SBN. This resonance is a quintet with a spacing of 61 Hz, corresponding to the indirect scalar coupling between $^{109}\text{Ag}$ and $^{14}$N (99.63% nat. ab., $I = 1$). The approximate $1 : 2 : 3 : 2 : 1$ relative intensity of the quintet is expected for coupling to two equivalent $I = 1$ nuclei and the crystal structure of SBN presenting a silver atom nitrogen-bonded by two bipy ligands. Note that the
The gradual change in morphology of the SBN block crystals to SBP needles upon exposure to ClO$_4^-$ solution confirms that the structural transformation between the two coordination polymers occurs by a solvent-mediated process, consistent with the PXRD patterns and MAS NMR spectra described above. The self propagating growth of a new crystal phase from a parent phase has been proposed to facilitate the exchange of anions in the inside core of [Ag(4,4-bipy)][BF$_4$] crystals undergoing the structural transformation to [Ag(4,4-bipy)][NO$_3$].

The reversibility of the anion exchange was demonstrated in our previous work and seven cycles of perchlorate uptake were monitored by PXRD. The metastability of the [Ag-bipy]$^+$ solids allow for the reversible solvent mediated transformation that can be controlled by the concentration of the incoming anions and temperature. The lower solubility of SBP as well as its higher stability due to the greater degree of π-stacking account for the rapid SBN to SBP transition. In contrast, the re-intercalation of nitrate is a less favoured process due to the larger hydration energy of nitrate. Additionally, SBN has a lower stability due to the partial π-stacking.

The regeneration of the SBN was further studied by recording the PXRD, $^{13}$C, $^{15}$N, $^{109}$Ag CP MAS NMR data and SEM images after treatment of the SBP material with excess nitrate at 70 °C under stirring (grey spectra, Fig. 3 and 4). The heat promotes the dissolution of the SBP polymers, while the excess nitrate shifts the dynamic equilibrium of the exchange to return to block shaped crystals with morphology identical to the as-synthesized SBN material (cf. black and grey SEMs, Fig. 4). The corresponding PXRD, $^{13}$C and $^{109}$Ag NMR data showed that although SBN has been mostly regenerated, approximately 10% of SBP is still present (as evidenced by integration of the NMR spectra and PXRD peaks).

4. Conclusion

This work shows by multiple complementary solid state methods that ClO$_4^-$ uptake by Silver 4,4′-Bipyridine Nitrate (SBN) [Ag-bipy][NO$_3$] occurs via a solvent-mediated process
to yield Silver 4,4'-Bipyridine Perchlorate (SBP). The structural features of the silver coordination polymers in terms of π-stacking and electrostatics concur with the dynamics of the anion exchange process. All three characterization methods show that the two crystalline phases are present throughout the anion exchange process. This study provides evidence of the structural flexibility displayed by the interaction of cationic [Ag-bipy+] MOFs with different adsorbates upon anion exchange. Such understanding of structural dynamics is crucial for the rational design of these and related MOFs toward the selective capture of environmental pollutant oxoanions such as perchlorate, chromate and arsenate. Reusability over many cycles is also crucial for the cost-effective deployment of these materials. The formation of new crystals on each exchange cycle circumvents the degradation issues of current ion exchange solids such as resins and LDHs that force them to be single-use.
