The use of carboxylic acids as traceless directing groups for regioselective C–H bond functionalisation

Marc Font,  Jacob M. Quibell,  Gregory J. P. Perry  and Igor Larrosa  *

The ability to selectively functionalise a specific C–H bond is a long-standing challenge due to the ubiquity of such bonds in organic molecules. One of the most common approaches to overcome this obstacle consists of installing directing groups into substrates to direct the functionalisation towards the desired C–H bond, leaving behind the directing group in the molecule. Alternatively, carboxylic acids have been employed as traceless directing groups that are easily removed after carboxylic acid-directed installation of the desired functionality. This review focuses on the development of this concept and its application to organic synthesis during the last decade.

Introduction

Building molecular complexity from simple, readily available building blocks has long been a fundamental aim of the synthetic chemist. Within organic chemistry C–H bond functionalisation has emerged as one of the most attractive methods for achieving greater intricacy in organic molecules.^{1–7} The ubiquitous presence of C–H bonds can provide a multitude of natural disconnections for further transformations whilst negating the need for the prefuctionalisation of starting materials, however with these

benefits come two inherent limitations: selectively activating just one C–H bond within chemically similar environments and overcoming the inert nature of the bond itself.

Finding a solution to these problems has generated a huge amount of interest in the synthetic community over the past few decades and thus far two major strategies have emerged. Firstly, using the innate reactivity of the organic molecule; *i.e.* using the acidity or nucleophilicity of a C–H bond to guide functionalisation to a specific location. The second strategy has come by way of employing the coordinating ability of other functional groups already installed on the molecule. These directing groups can guide the reactivity of a transition metal to the selected site, allowing the replacement of the C–H bond

Marc Font

Marc Font studied Chemistry at the University of Girona, where he was awarded his MChem in 2011. In 2015 he earned his PhD in Chemistry from the University of Girona on the elucidation of the mechanisms of the coinage metal-catalysed cross-coupling reactions under the guidance of Dr Xavi Ribas and Dr Miquel Costas. His PhD studies included a research period with Prof. John F. Hartwig at the University of California at Berkeley. Following

this, he joined the group of Prof. Igor Larrosa at the University of Manchester pursuing postdoctoral studies on the development of novel methods for C–H functionalisation.

Jacob M. Quibell

Jacob Quibell completed his undergraduate and masters studies at the University of Edinburgh. During this time he spent a year in the University of Alicante working under the supervision of Prof. Francisco Foubelo investigating the use of sulfinylamines in stereo-selective nitro-mannich reactions. He then returned to Edinburgh to work with Dr Stephen Thomas on iron-catalysed hydrofunctionalisations. He is now in his second year of his PhD studies with Prof.

Igor Larrosa at the University of Manchester focussing on decarboxylative transformations.

with C–C, C–O, C–N or other C–heteroatom bonds. These revelations have fuelled the growth of a huge repository of diverse directing groups (Scheme 1(i)), many of which operate at the highest level of reactivity and selectivity.⁸ However, if these moieties cannot be found in natural or commercially available compounds then the instalment of these groups can have a costly effect on the step and atom economy. This is further exasperated if the removal of the directing group is later on required, creating additional steps in the procedure (Scheme 1(ii)); in many ways reducing the central dogma of C–H activation to redundancy.⁹ A solution to this has been partially provided by the use of transient, catalytic directing groups which have the ability to tether themselves to a pre-existing part of the molecule and direct the C–H functionalisation before its release (Scheme 1(iii)). Although much progress has been made in the development of these directing groups, mainly through the reversible formation of phosphinite, imine or enamine functionalities, they still require a specific functionality on the molecule on which to tether.¹⁰

An ideal situation would be to use a directing group inherent to a number of natural and commercially available compounds which can also be tracelessly removed. Within these specifications

an attractive functionality is the carboxylate moiety. The abundance of carboxylates in organic molecules and the versatility when considering further transformations¹¹ makes it an ideal candidate for directing C–H bond functionalisations; in addition the removal of the carboxylate by extrusion of CO₂ allows traceless operation of the directing group (Scheme 1(iv)).¹²

Carboxylic acids are cheap synthons that can be easily prepared by a number of methods; ranging from the oxidation of a diversity of functional groups such as olefins, aldehydes, alcohols or even alkanes to the hydrolysis of nitriles, acyl chlorides, esters or anhydrides. In addition, their synthesis *via* formation of organolithium or Grignard reagents followed by quench with CO₂ has large precedence in the literature.¹³ More recently, also modern transition metal catalysis has been applied to carboxylation methods leading to more efficient and greener protocols for the preparation of carboxylic acids.¹⁴

This review will mainly focus on the utility of the carboxylate moiety in the *ortho*-functionalisation of benzoic acids before its subsequent removal *via* decarboxylation. With this goal in mind it is first pertinent to discuss the trends in transition metal-catalysed protodecarboxylations to better understand the requirements for traceless directing groups in C–H transformations.

Gregory J. P. Perry

Gregory Perry received his MChem from the University of Liverpool (UK) where he worked under the supervision of Professor P. Andrew Evans. He then joined the group of Professor Igor Larrosa and was awarded his PhD from the University of Manchester (UK) in 2016. His doctoral studies focused on the development of decarboxylative and C–H transformations for organic synthesis. He is currently a Postdoctoral Fellow at Nagoya University (Japan) working in the lab of Professor Kenichiro Itami.

Igor Larrosa

Igor Larrosa graduated in Chemistry from the University of Barcelona (1999) where he also completed an MChem (2000) and a PhD degree (2004) with Profs Felix Urpi and Pere Romea. After a research period in Prof. Erick M. Carreira's laboratories at ETH (Zurich), Igor moved as a Post-doctoral Researcher to Imperial College London to work in Prof. Anthony G. M. Barrett's group. In September 2007 he started his independent career as a Lecturer at Queen Mary University of London. In 2011, Igor was awarded a European Research Council starting grant. Since 2014 Igor holds a Chair in Organic Chemistry at the University of Manchester.

Transition metal-promoted protodecarboxylation

Many methods exist for the protodecarboxylation of benzoic acids, however, only examples that bear some relevance to further coupling reactions will be discussed here. For a more comprehensive outlook on protodecarboxylation the reader is directed to some representative reviews.^{15,16}

Reports of protodecarboxylation date back to the mid-20th century¹³ yet the field remained in its infancy until Gooßen *et al.* disclosed the first copper-catalysed version.¹⁷ The Gooßen group showed that the presence of nitrogen donor ligands and an NMP/quinoline solvent mix were required for efficient reactivity. They also observed that electron-deficient benzoic acids were more reactive than electron-rich ones (e.g. **1a** vs. **2a**, Scheme 2). Interestingly, *ortho*-substituted benzoic acids generally show higher reactivity than their *meta* or *para*-substituted analogues, however, good reactivity was found by employing a modified phenanthroline ligand **L1** (e.g. **2b** vs. **2c**, Scheme 2). This seminal report paved the way for other similar methods to be developed with changes to the ligand system allowing for lower temperatures¹⁸ to be used and microwave heating giving a reduction in reaction times.¹⁹ The increased reactivity of *ortho*-substituted substrates provoked an investigation into the mechanism of these reactions. Through DFT studies the groups of Su²⁰ and Gooßen²¹ found a plausible transition state **8** in which the Cu inserts into the aryl carboxyl bond (Scheme 3A). Further studies by Su and co-workers showed the effect of the *ortho*-substituent to be twofold: 1° effect- the extra sterical stress of an *ortho*-substituent raises the energy of the reactant thus

Scheme 3 Proposed mechanism for the copper-catalysed protodecarboxylation of aromatic carboxylic acids (A) and delineating the 1° (B) and 2° *ortho*-effect (C).

Scheme 2 Copper-catalysed protodecarboxylation of aromatic carboxylic acids. ^a GC yield.

decreasing the overall barrier to decarboxylation (Scheme 3B). 2° effect- *ortho*-substituents that are capable of coordination to the copper lower the energy of the transition state, decreasing the overall energy barrier to decarboxylation (Scheme 3C).

Silver was then shown to be a suitable surrogate for the copper-catalysed process with simultaneous publications coming from the groups of Gooßen²² and Larrosa.^{23,24} These reports showed that both electron withdrawing (e.g. **12a**, Scheme 4) and electron donating (e.g. **16a**, Scheme 4) substituents were compatible with the process, however, electron deficient substrates were generally more reactive (Scheme 4). The key difference between Ag- and Cu-catalysed protodecarboxylations is that *ortho*-substituents are a necessity in Ag-catalysed procedures, but lower temperatures can be used (120 vs. 160 °C).

DFT studies revealed that the reaction proceeded through a transition state similar to that observed with the copper-catalysed process **19** and the 1° and 2° *ortho* effects exhibited in the copper systems were also applicable to the silver-catalysed protocols (Scheme 5).

In addition it was revealed that a third effect was in place; it was found that a build-up of negative charge on the carbon *ipso* to the carboxylate group occurred in the transition state.²⁵ In light of this, it is proposed that benzoic acids bearing electron-withdrawing substituents are more reactive than those bearing electron-donating substituents as they can better stabilise this

build-up of negative charge, therefore, facilitating the decarboxylation step.

Palladium has also been shown to be an effective catalyst in the protodecarboxylation of benzoic acids. Kozłowski showed that highly electron rich substrates bearing two *ortho*-substituents underwent decarboxylation at relatively low temperatures; however this methodology was severely limited. In order for mono-*ortho*-substituted benzoic acids **28** and less electron rich benzoic acids **29** to undergo decarboxylation a stoichiometric amount of palladium was required (Scheme 6).²⁶ Mechanistic studies by various groups¹⁴ have shown a very distinct reaction profile for the palladium system compared to those for copper and silver; firstly the decarboxylation proceeds through a 4-membered transition state with no interaction with the carboxyl carbon (see **31** vs. **8** and **19**, Scheme 7).

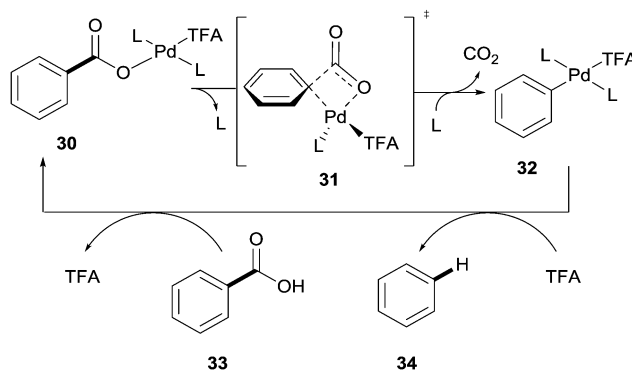

i) catalytic Pd

ii) stoichiometric Pd

Scheme 6 Palladium-promoted protodecarboxylation of aromatic carboxylic acids.

Scheme 7 Proposed mechanism for the palladium-catalysed protodecarboxylation of aromatic carboxylic acids.

Secondly the rate determining step was proposed to be the protodemetalation of **32** rather than the decarboxylation. Although it was conceded that this may change between different substrates due to the small difference in barriers ($\sim 2 \text{ kcal mol}^{-1}$) of each step. The authors also noted that the benzoic acid was likely unable to mediate the protodemetalation of the palladium-aryl species and so TFA is necessary in this reaction to facilitate this step.

Another transition metal relevant to coupling reactions that has been shown to promote the protodecarboxylation of benzoic acids is rhodium.²⁷ In this context, Zhao showed that highly activated di-*ortho*-substituted carboxylic acids could be effectively protodecarboxylated in the presence of Rh(I) species. The protocol is exclusive to fluoro/methoxy substituted benzoic acids and some heteroaromatic carboxylic acids yet is unique in the fact that it uses a phosphine ligand and water as a co-solvent (Scheme 8).

Scheme 8 Rhodium-catalysed protodecarboxylation of (hetero)aromatic carboxylic acids.

Carboxylic acids as traceless directing groups

The potential synthetic use of combining decarboxylation of carboxylic acids with their broad use as directing groups¹² has incited a boom in methods for the sequential functionalisation/decarboxylation of benzoic acids over the last ten years. These methods can be largely divided into three classes: (1) two-step transformations using multi-metallic systems; (2) single-step transformations using multi-metallic systems and (3) single-step transformations using mono-metallic systems (Scheme 9).

Functionalisation/decarboxylation reaction involving two metals and two steps

The first method that revealed the potential of benzoic acids to direct C–H bond functionalisation tracelessly came from Daugulis and co-workers.²⁸ A seminal publication from the group revealed an efficient process for the *ortho*-arylation of a variety of benzoic acids with electronically diverse aryl chlorides or aryl iodides. Importantly, they then went on to illustrate that the carboxyl group in the biaryl product could be removed *via* the copper-catalysed protodecarboxylation methodology disclosed by Gooßen *et al.* (Scheme 10).¹⁷ In this example 4-toluic acid **38** was coupled with 1-iodo-3,5-bis(trifluoromethyl)benzene **39** *via* palladium-catalysed *ortho* C–H activation with a superstoichiometric silver acetate additive. The biaryl carboxylic acid was then isolated prior to being submitted to the conditions for the

Scheme 10 Palladium-catalysed *ortho* C–H bond arylation of benzoic acids followed by copper-catalysed protodecarboxylation. ^a 165 °C. ^b O₂ (5 atm).

protodecarboxylation described by Gooßen giving product **40** in a 51% overall yield (Scheme 10). This was the first demonstration of carboxylic acids acting as a traceless directing group in C–H bond functionalisation however the need for purification before removing the carboxylic acid decreased the step economy of the process.

In 2015, Gooßen *et al.* developed a procedure for the *ortho*-arylation of benzoic acids catalysed by iridium that was also amenable to subsequent protodecarboxylation in a one-pot fashion (Scheme 11).²⁹ The arylation used arenediazonium salts as the coupling partners with AgCO₃ and Li₂CO₃ as additives. In this case, purification between steps was not required and the resulting *meta*-functionalised aryl **43** was formed after the reaction mix was subjected directly to the copper-mediated protodecarboxylation conditions developed in their laboratories.

In an analogous publication Zhang extended the scope of the sequential *ortho*-arylation/protodecarboxylation of *meta*-substituted benzoic acids (Scheme 12, conditions A).³⁰ Furthermore, they also revealed that, upon changing the reaction conditions, they could effect a carbonylation or hydroxylation sequence, followed by protodecarboxylation. The functionalisation conditions used were originally developed by the groups of Larrosa,³¹ Ge,³² and Yu³³ for the *ortho*-arylation, carbonylation and hydroxylation of benzoic acids respectively. The novelty of this report by Zhang is the removal of the directing group after the functionalisation to provide a range of *para*-substituted arenes in good to excellent overall yields. However, a work-up was required between the functionalisation and the decarboxylation steps.

Scheme 9 Classification of the methods for directed C–H functionalisation followed by decarboxylation.

Scheme 11 Iridium-catalysed *ortho* C–H bond arylation of benzoic acids followed by copper-mediated protodecarboxylation.

Scheme 12 Sequential palladium-catalysed *ortho* C–H bond arylation/protodecarboxylation of *m*-substituted benzoic acids.

Miura and co-workers further developed the system of the traceless directing group into a one-pot process.^{34,35} Using rhodium to catalyse the coupling followed by silver to facilitate the decarboxylation, the process obviated the requirement of a work-up between steps (Scheme 13). The scope was largely restricted to benzoic acids containing electron-rich substituents; phenyl and fluoro substituents were also shown to react giving moderate yields (Scheme 13, 53, 54). However, both the

Scheme 13 Rhodium-catalysed two-step synthesis of stilbene derivatives.

Scheme 14 Iridium- and palladium-catalysed 2-step synthesis of *N*-aryl-sulfonamides. ^a Conditions 2nd step: Cu₂O (0.5 equiv.), Phen (1 equiv.), DMA, N₂, 170 °C, 12 h.

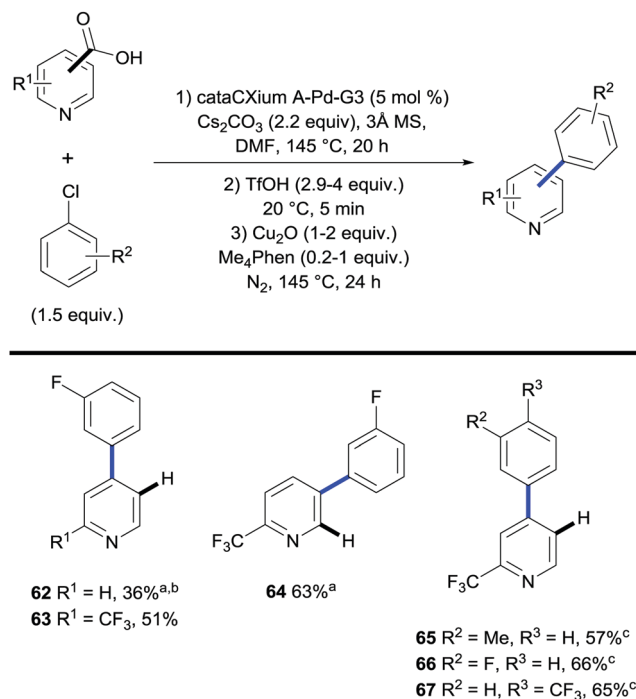

functionalisation and the protodecarboxylation steps required excess AgOAc.

A protocol for the one-pot C–H amidation/decarboxylation of benzoic acids was reported by Chang and co-workers in which *ortho*-substituted benzoic acids reacted with sulfonyl azides in the presence of an iridium catalyst followed by a palladium-catalysed protodecarboxylation event (Scheme 14).³⁶ The decision to use a palladium catalyst for the protodecarboxylation step was inspired by the previous report by Kozłowski and co-workers (Scheme 6).²⁶

The results yielded *meta*-substituted arenes in moderate to high yields. Again electron rich benzoic acids were mainly used although some electron deficient benzoic acids such as 2,4-dichlorobenzoic acid (Scheme 14, 59) were also shown to react in high yields. This is quite remarkable given that decarboxylation of electron-deficient substrates by palladium is not favored. They also investigated the feasibility of *meta*-substituted benzoic acids in the same system; however, the absence of an *ortho*-substituent with respect to the carboxylate group ensured the lack of reactivity in the palladium-catalysed protodecarboxylation step. The authors went on to show that copper was capable of achieving this transformation although it required stoichiometric amounts of the metal in question (Scheme 14, 61).

Recently Larrosa *et al.* disclosed a procedure for the *ortho*-arylation of pyridine carboxylic acids (Scheme 15).³⁷ This methodology allowed for the selective functionalisation at the C3 or C4 positions of the pyridine ring. Pyridines are particularly difficult substrates to undergo functionalisation as the ability for the

Scheme 15 Palladium-catalysed/copper-mediated 2-step synthesis of phenyl pyridines. ^a Conditions 1st step: reaction performed with $\text{Pd}(\text{OAc})_2$ (5 mol%) and $\text{PdAd}_2\text{nBu-HI}$ (10 mol%). ^b 40 h arylation time. ^c Phen (0.2 equiv.) instead of Me_4Phen .

nitrogen atom to coordinate to the metal often kills any reactivity. It is thought that the inclusion of a carboxyl group in the substrate can out-compete coordination by the nitrogen atom, therefore leading to an efficient and selective functionalisation.

A Buchwald third generation precatalyst (cataCXium A-Pd-G3) was found to be the optimal catalyst for the arylation in a DMF solvent with Cs_2CO_3 as the base. Both chloroarenes and bromoarenes substituted with electron donating and electron withdrawing groups were found to be suitable electrophiles under these conditions. Generally, electron deficient pyridine carboxylic acids gave better reaction outcomes – likely due to the lower coordinating ability of the N-atom – whereas electron-rich substrates gave diminished yields.

A one-pot arylation/decarboxylation process was then developed giving access to arylated pyridines. Using the previously optimised conditions for arylation the reaction mixture was then subjected to the conditions for copper-mediated decarboxylation using stoichiometric copper oxide and a methyl-substituted phenanthroline ligand Me_4Phen . The two conditions were shown to be compatible with each other provided triflic acid was added prior to the decarboxylation step.

Functionalisation/decarboxylation reaction involving two metals and one step

The field of regioselective transition metal-catalysed C–H bond functionalisation *via* traceless directing groups has evolved

Scheme 16 Palladium-catalysed one-step 3-vinylation/decarboxylation of heteroarene carboxylic acids. ^a 120 °C. ^b Without LiOAc .

towards methods consisting of tandem functionalisation/decarboxylation reactions, thereby accelerating the overall reaction times and simplifying the experimental protocols. Such approaches add extra intricacy to the reaction as the decarboxylation of the starting material must be avoided to obtain synthetically useful reaction outcomes. The viability of this approach was first demonstrated by Miura and co-workers. The authors developed a protocol for the regioselective palladium-catalysed oxidative alkenylation/decarboxylation of (benzo)furan, (benzo)thiophene and *N*-protected indole and pyrrole carboxylic acids in good to excellent yields with largely good regioselectivity (Scheme 16).³⁸ Alkyl acrylates and styrene proved to be suitable olefin coupling partners for this method. Importantly, this methodology allows for the direct vinylation of 1-methylindole-3-carboxylic acid in the less activated C2 position, whereas, under similar conditions, the alkenylation of *N*-methylindole proceeds exclusively at the C3 position (Scheme 17A and B). One of the limitations of this method is that selective C3-vinylation of (benzo)thiophene 2-carboxylic acid proved unsuccessful giving rise to mixtures of 2- and 3-olefination products; presumably due to initial protodecarboxylation of the starting heteroaromatic carboxylic acid material followed by subsequent non-directed coupling with the resulting thiophene or benzothiophene although alternatively decarboxylative alkenylation could account for such regioselectivity. However, in a following report by the Miura group, they addressed this issue by developing a rhodium-catalysed protocol that enabled the selective C3-olefination of those substrates as well as benzofuran, *N*-methylpyrrole and *N*-methylindole 2-carboxylic acids.³⁵

Scheme 17 (A) Palladium-catalysed C2-vinylation/decarboxylation of indole-3-carboxylic acids. (B) Palladium-catalysed 3-vinylation of *N*-methylindole.

Maiti and co-workers took advantage of the carboxylic acid traceless directing group strategy to achieve a regioselective alkenylation of arenes providing a new route towards branched

Scheme 18 Palladium-catalysed branched C–H bond alkenylation of arenes with cinnamic acids. ^a Reaction performed with $\text{Pd}(\text{O}i\text{Pr})_2$, bpy. ^b 140 °C. Reaction performed with bpy, Ac_2O (1 equiv.), $\text{Cu}(\text{OAc})_2 \cdot \text{H}_2\text{O}$.

alkenes, achieving the opposite selectivity to the traditional linear alkene-forming Mizoroki–Heck reaction.³⁹ The authors approached the switch in selectivity by using cinnamic acids as the coupling partners. Their protocol involved a palladium/copper system that performed a dehydrogenative arene C–H bond alkenylation/decarboxylation sequence affording 1,1-disubstituted olefins with high selectivity (Scheme 18). The applicability of the method is limited by the use of the arene in vast excess and the poor *ortho/meta/para* regioselectivity on substituted arenes.

Hong and co-workers approached the synthesis of (hetero)acenes from di(hetero)aryl acetic acids and ethyl acrylate by developing a palladium-catalysed cascade reaction involving a C–H bond functionalisation/decarboxylation sequence (Scheme 19).⁴⁰ This reaction is believed to be initiated with the carboxylate-directed palladium-catalysed C–H vinylation reaction, followed by C–H bond cyclisation. Upon decarboxylation and isomerisation of the double bond, the final (hetero)acene scaffold was obtained. This protocol gives rise to a new step- and atom-economical route

Scheme 19 Palladium-catalysed synthesis of (hetero)acenes by reaction of di(hetero)aryl acetic acids with ethyl acrylate.

towards complex linearly fused polycyclic aromatic hydrocarbons with very specific substitution patterns.

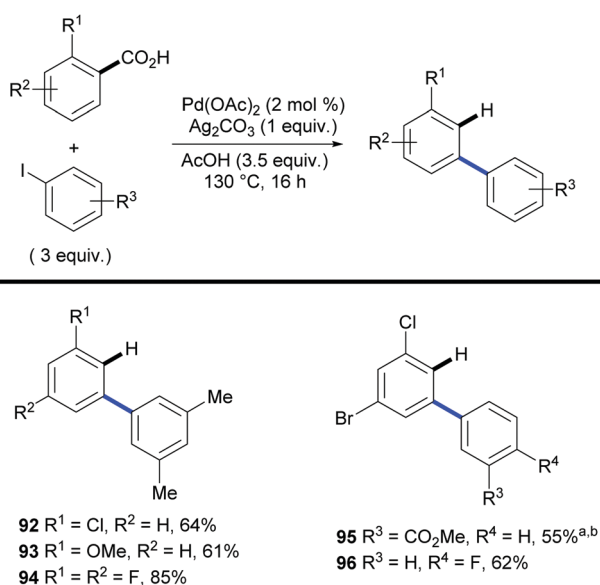

As highlighted by Miura's and Maiti's examples, one of the main features of the aforementioned approach is the ability to achieve regioselectivities that are often unattainable by using traditional methods. This was further demonstrated in 2011 in a paper by Larrosa and co-workers.⁴¹ The authors applied the traceless directing group strategy to *ortho*-substituted benzoic acids to achieve *meta*-substituted biaryl scaffolds using aryl iodides as the coupling partners and Pd(OAc)₂ as the catalyst (Scheme 20). This protocol exploited the preference of palladium to decarboxylate electron rich bis-*ortho*-substituted benzoic acids (Scheme 6) to tackle the selective protodecarboxylation of the arylated benzoic acid product over the benzoic acid starting material. This provided the desired reactivity obtaining the *meta*-arylated product. Remarkably, the scope of the reaction included electron-deficient benzoic acids, which were previously considered highly deactivated substrates for the palladium-catalysed decarboxylation step (e.g. **92** and **94–96**, Scheme 20). The authors demonstrated that palladium selectively decarboxylates the arylated products by submitting both the starting benzoic acid **97** and arylation product **98** to different silver- and palladium-promoted decarboxylations. While the silver-catalysed conditions developed within the Larrosa group²³ afforded 3 times more decarboxylation of the starting benzoic acid **97** than that of the arylated product **98** (Table 1, entry 1), employing silver in AcOH at 130 °C did not afford any decarboxylation product (Table 1, entry 2). Palladium instead was shown to be able to selectively decarboxylate the arylation product **98** in the arylation/decarboxylation reaction conditions (Table 1, entry 3) with no decarboxylation of starting benzoic acid **97**. In addition, when both benzoic acids were submitted to the reaction conditions only the arylation product **98** underwent decarboxylation (Table 1, entry 4). The authors also

Table 1 Competition experiments to determine the catalyst responsible for the decarboxylation step of arylated benzoic acids

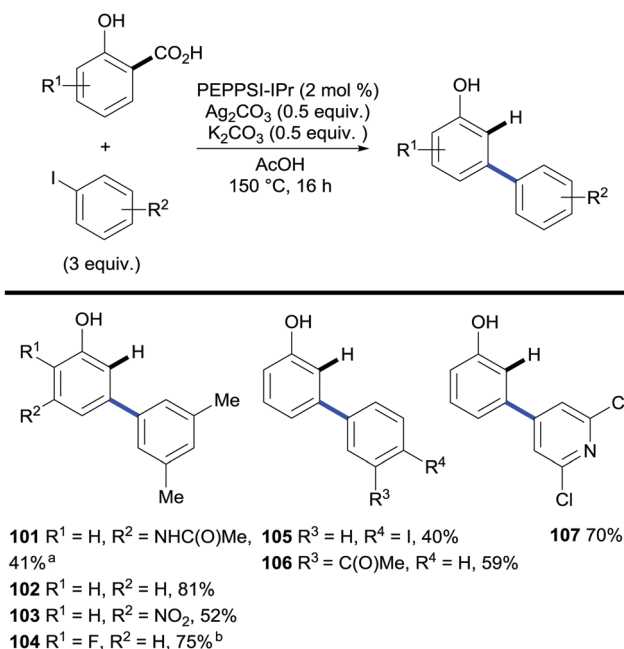

Entry	Conditions	Yield 99 (%)	Yield 100 (%)
1	10 mol % Ag ₂ CO ₃ , DMSO, 120 °C, 4 h	18	5
2	1 equiv. Ag ₂ CO ₃ , AcOH, 130 °C, 2 h	0	0
3	2 mol % Pd(OAc) ₂ , AcOH, 130 °C, 2 h	0	22

found that the protodecarboxylation of the arylated product can be avoided by adding sub-stoichiometric amounts of K₂CO₃ to the reaction providing a reliable route towards 2-aryl-6-substituted benzoic acids.³¹

Next, Larrosa and co-workers investigated the tandem arylation/decarboxylation of widely available salicylic acids. By finely tuning the reaction conditions they found PEPPSI™-IPr to be a superior catalyst for this transformation yielding a wide array of *meta*-arylated phenol compounds, which have traditionally been a challenging class of compounds to access (Scheme 21).⁴²

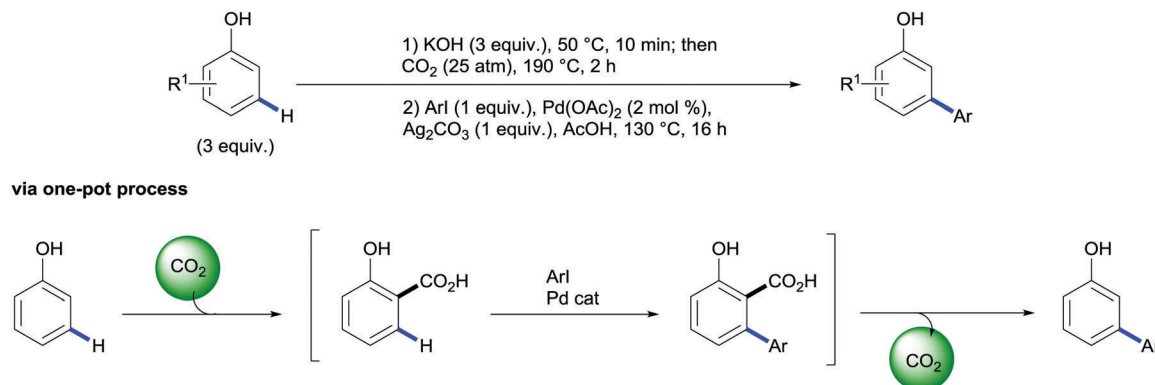

Scheme 20 Synthesis of *m*-substituted biaryls via palladium-catalysed C–H bond arylation/decarboxylation of 2-substituted benzoic acids. ^a After 16 h, 0.25 equiv. of Ag₂CO₃ in 2.5 ml DMSO added and stirred for 3 h at 130 °C. ^b 7 equiv. AcOH.

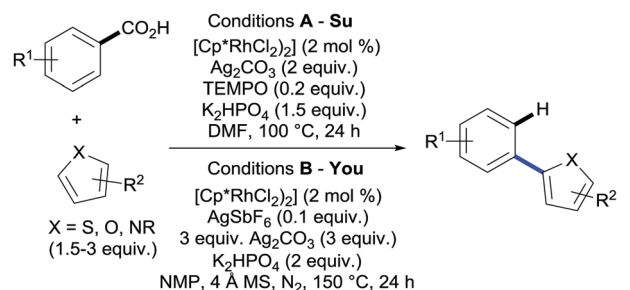

Scheme 22 Synthesis of *m*-arylated phenols via one-pot sequential carboxylation followed by palladium-catalysed C–H bond arylation/decarboxylation of phenols.

Importantly, the authors also demonstrated that this methodology tolerates the replacement of the silver-based halide scavenger by an ammonium organic salt (NMe₄Cl) leading to a more environmentally friendly and cheaper protocol.⁴³ Taking advantage of this protocol the authors designed a novel approach for the *meta*-arylation of phenols consisting of a two-step one-pot synthetic sequence involving an initial Kolbe–Schmitt carboxylation followed by the aforementioned tandem arylation/decarboxylation reaction without exacerbating the reaction scope and yields (Scheme 22).⁴⁴ This example shows that by using the traceless directing group relay strategy a new mode of reactivity for phenols is enabled and their inherent *ortho/para* selectivity for electrophilic aromatic substitutions can be overridden. Alternatively, salicylaldehydes have been demonstrated to be suitable building blocks of *meta*-arylated phenols. In a related strategy, Larrosa and co-workers reported the domino oxidation/C–H arylation/protodecarboxylation reaction of salicylaldehydes. Investigation on the nature of this transformation revealed the implication of palladium in the oxidation step indicating a plausible Wacker-type process.⁴⁵

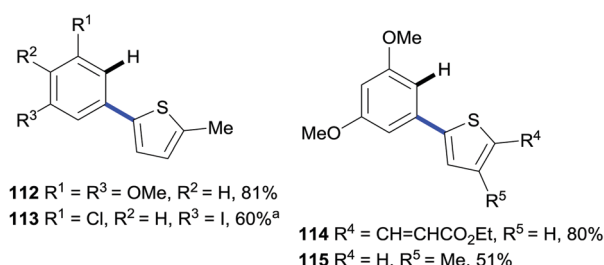

Very recently the *ortho* C–H bond arylation of benzoic acids and heteroaromatic carboxylic acids has been reported to take place under ruthenium catalysis by the groups of Ackermann,⁴⁶ Gooßen,⁴⁷ Larrosa⁴⁸ and Weix.⁴⁹ Gooßen's methodology also described that the addition of a copper catalyst and raising the reaction temperature up to 190 °C triggered the concomitant

protodecarboxylation affording two examples of *meta*-substituted biaryls (Scheme 23).

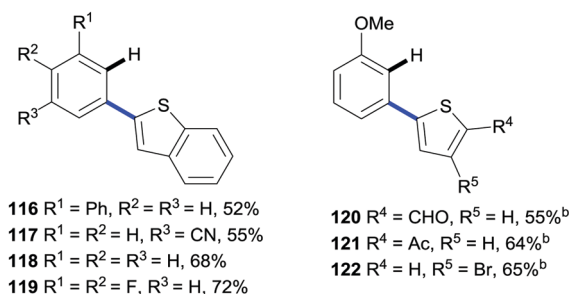

The Su and the You groups published in 2015 the rhodium-catalysed oxidative C2-(hetero)arylation of heteroaromatic moieties

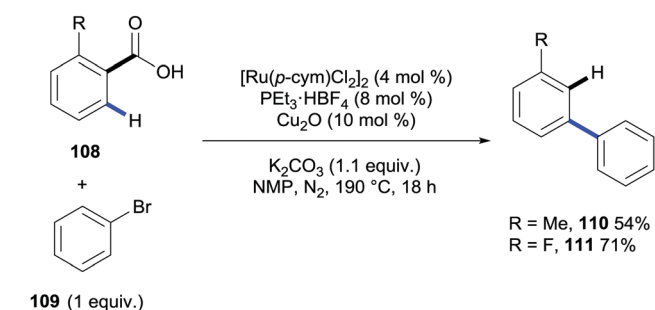

Conditions A

Conditions B

Scheme 24 Rhodium-catalysed C2-arylation of thiophenes. ^a Reaction conditions: [(Cp*RhCl₂)₂] (4 mol%), Ag₂CO₃ (3 equiv.), Li₂CO₃ (1.5 equiv.), TEMPO (0.2 equiv.), DMF, 100 °C, 24 h, then 140 °C, 6 h. ^b AgSbF₆ (0.2 equiv.), 48 h.

Scheme 23 Ruthenium- and copper-catalysed system for the arylation/decarboxylation of benzoic acids.

(i.e. (benzo)thiophenes, (benzo)furans, *N*-protected indoles, etc.) with aromatic carboxylic acids in the presence of a silver salt (Scheme 24).^{50,51} Forcing temperatures were needed when 2,4-dimethoxybenzoic acid is replaced for a less electron rich coupling partner, presumably to fully trigger the protodecarboxylation event.

Remarkably, these protocols involve double C–H activation processes obviating the need for prefunctionalised starting materials as aryl donors although large amounts of silver are needed. Also, they describe the regioselective cross-coupling between two heteroaromatic moieties, transformations that have traditionally proven to be very challenging.

The applicability of this strategy is not restricted to the formation of C–C bonds but C–heteroatom bond-forming protocols have recently started to flourish. Gooßen and co-workers developed the alkoxylation of potassium aryl benzoates with concomitant protodecarboxylation mediated by a copper/silver system and using trialkylborates as the alkoxide source (Scheme 25).⁵²

N-Aryl benzamides have also been accessed through amidation/decarboxylation of benzoic acids under rhodium catalysis with isocyanates (Scheme 26).⁵³ This method uses catalytic amounts of Cu₂O to promote protodecarboxylation of the amidation product. However, the authors showed that in its absence the desired

Scheme 25 Copper-mediated C–H bond alkoxylation/decarboxylation of potassium aryl benzoates. ^a B(OR)₃ (5 equiv.). ^b Quinoline (0.19 equiv.).

Scheme 26 Rhodium-catalysed C–H bond amidation/decarboxylation of benzoic acids.

Scheme 27 Iridium-catalysed B–H bond alkenylation/decarboxylation of *o*-carborane benzoic acids.

decarboxylated product is obtained and although lower yields were exhibited, this showed the ability of rhodium to promote protodecarboxylation. The authors subsequently reported that using very similar conditions the rhodium catalyst can be replaced by ruthenium thus eliminating the necessity of copper for the decarboxylation step.⁵⁴

Remarkably, the use of carboxylic acids as traceless directing groups has also inspired researchers in other fields to develop unprecedented transformations. In this regard, a series of 4-*B*-alkenylated *o*-carborane derivatives have been accessed regioselectively for the first time from their parent *o*-carborane-1-carboxylic acid *via* an iridium-catalysed carboxylate-directed B[4]–H alkenylation/protodecarboxylation sequence (Scheme 27).⁵⁵

Functionalisation/decarboxylation reaction involving one metals and one step

In these processes both the C–H functionalization and the protodecarboxylation steps are carried out by the same transition metal,

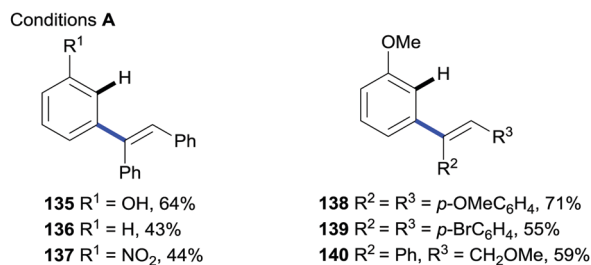

Scheme 28 Palladium-catalysed C2-arylation/decarboxylation of *N*-alkyl-indole-3-carboxylic acids.

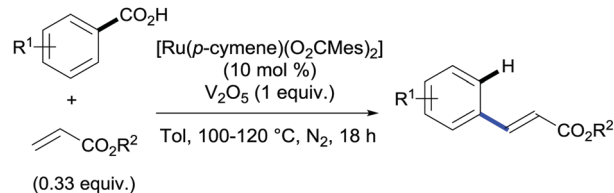

thus avoiding the need for catalyst compatibility and/or additional reaction steps.

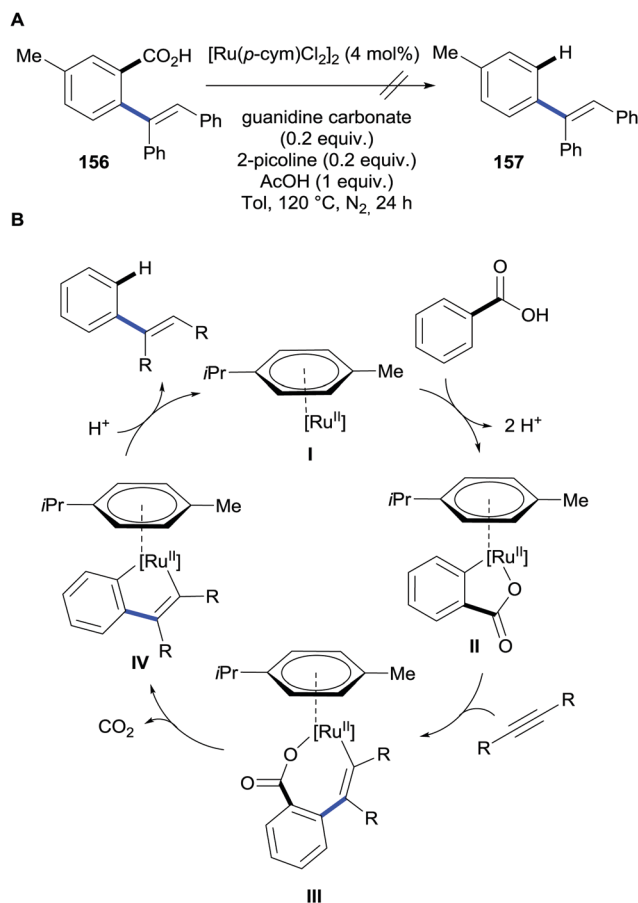

The first reported method to find the appropriate choice of catalyst for such reactions dates back to 2012. Lee and co-workers, in a similar protocol to Miura's vinylations of hetero-aromatic carboxylic acids discussed in the previous section (Schemes 16 and 17),^{35,38} designed and prepared a carbene-based Pd(0) catalyst (cat3, Scheme 28) which was applied to both the arylation/decarboxylation and decarboxylative arylation of various heteroaromatic systems using aryl bromides and aryl chlorides as the coupling partners. The authors showed that C2-arylation/decarboxylation of *N*-alkylindole-3-carboxylic acid

Scheme 29 Ruthenium-catalysed C–H bond alkenylation/decarboxylation of benzoic acids via hydroarylation of alkynes. *E* : *Z* ratios shown in parenthesis.

Scheme 30 Ruthenium-catalysed C–H bond alkenylation/decarboxylation of benzoic acids via oxidative alkenylation.

Scheme 31 (A) Attempts for the ruthenium-catalysed decarboxylation of alkenyl benzoic acids. (B) Proposed mechanism for the C–H bond ruthenium-catalysed alkenylation/decarboxylation of benzoic acids via hydroarylation of alkynes.

occurred whilst C2-decarboxylative arylation took place when *N*-alkylindole-2-carboxylic acid was the substrate of choice (Scheme 28). More recently, ruthenium has proven to be an exceptional catalyst at promoting protodecarboxylation events after *ortho*-C–H bond functionalisation reactions.

Further to the ruthenium-catalysed amidation/decarboxylation discussed in the previous section,⁵⁴ the Ackermann,⁵⁶ Gooßen,^{57,58} Hartwig and Zhao⁵⁹ laboratories have independently demonstrated the ability of ruthenium to catalyse C–H bond olefination/decarboxylation sequences to yield alkenylarenes under remarkably mild conditions.⁶⁰

These articles feature similar redox-neutral processes *via* stereoselective *syn*-hydroarylation reactions employing biaryl alkynes and aryl-alkyl alkynes as coupling partners (Scheme 29).

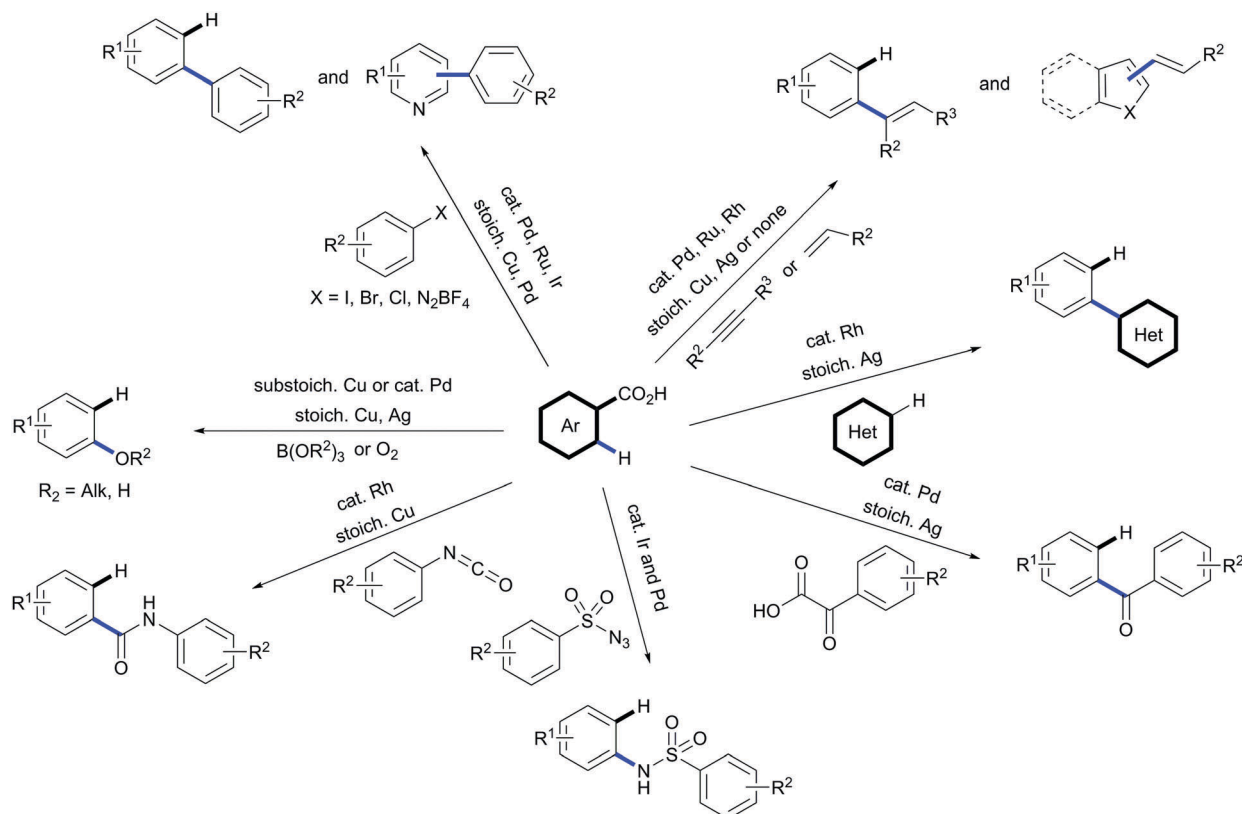

In addition, Ackermann also reports that acrylates can engage in oxidative C–H bond alkenylation/decarboxylation reactions (Scheme 30). Importantly, these methods provide routes to access both *meta*- and *para*-alkenylarenes depending on the substitution pattern on the parent benzoic acid.

Opposite to most methods, these reactions do not operate through a functionalisation/protodecarboxylation sequence. This was demonstrated by submitting the alkenylated benzoic acid product to the standard reaction conditions; this afforded no protodecarboxylation product (Scheme 31A). Thus, the decarboxylation takes place simultaneously to the alkenylation reaction. The authors proposed the mechanism depicted in (Scheme 30B) that is initiated by carboxylate-directed ruthenium C–H bond

metalation to generate intermediate II. Subsequently the alkyne moiety is inserted into the C–Ru bond forming intermediate III that upon extrusion of CO₂ releases the product and regenerates the ruthenium catalyst that restarts the catalytic cycle. This mechanism completely prevents a second alkenylation at the other *ortho* position of the carboxylate.

Conclusions

In a field largely dominated by non-removable directing groups, the use of carboxylic acids as traceless directing groups for C–H functionalisation has emerged as a potent new concept in synthetic organic chemistry. By putting this strategy to use, not only new routes for accessing a wide variety of challenging substitution patterns have been discovered but new reactivities have been unveiled that may influence complimentary transformations. These methodologies are especially valuable due to the fact that carboxylic acids are cheap and readily available. During the last decade this strategy has witnessed major advances; from methods that needed two steps promoted by two different transition metals and purification of the material between steps to protocols using a catalyst able to promote tandem functionalisation/decarboxylation sequences on its own. However, the possibilities encompassed by this strategy are immense and only a few classes of transformations on a small range of substrates have been explored to date (Scheme 32). The field

Scheme 32 Scope of available transformations by using carboxylic acids as traceless directing groups.

of traceless directing groups needs to evolve towards broadening the reactivity allowed by such methods, and in line with the latest developments in the field, accelerating the synthetic routes towards target molecules bearing challenging substitution patterns in a more sustainable manner.
