# Photo-induced radical polarization and liquid-state dynamic nuclear polarization using fullerene nitroxide derivatives†

Guoquan Liu,<sup>‡a</sup> Shu-Hao Liou,<sup>‡a</sup> Nikolay Enkin,<sup>a</sup> Igor Tkach<sup>a</sup> and Marina Bennati<sup>‡\*ab</sup>

We report on radical polarization and optically-driven liquid DNP using nitroxide radicals functionalized by photoexcitable fullerene derivatives. Pulse laser excitation of the fullerene moiety leads to transient nitroxide radical polarization that is one order of magnitude larger than that at the Boltzmann equilibrium. The life time of the radical polarization increases with the size of the fullerene derivative and is correlated with the electronic spin-lattice relaxation time  $T_{1e}$ . Overhauser NMR signal enhancements of toluene solvent protons were observed under steady-state illumination, which replaced microwave irradiation.

## Introduction

Dynamic nuclear polarization (DNP) is a rapidly developing method to enhance the sensitivity of nuclear-magnetic resonance (NMR) techniques.<sup>1</sup> The method transfers spin polarization from electrons to coupled nuclear spins by microwave (MW) irradiation. To achieve this, polarizer molecules – usually nitroxide radicals – are mixed in solution with the target molecules, from which the NMR spectrum is recorded. For electron spins in thermal equilibrium prior to MW pumping, NMR signal enhancements up to 3 orders of magnitude have been reported,<sup>2</sup> with a theoretical limit determined by the gyromagnetic ratios  $\gamma$  of electrons and nuclear spins (for  $^1\text{H}$ :  $|\gamma_e|/\gamma_H = 658$ ). DNP in liquids is based on electron–nuclear cross relaxation, the so-called Overhauser effect, and the NMR signal enhancement  $\varepsilon$  is well described by the following equation:<sup>3–5</sup>

$$\varepsilon = 1 - s_{\text{eff}} f \xi \cdot |\gamma_e|/\gamma_I \quad (1)$$

where  $\gamma_I$  is the nuclear gyromagnetic ratio involved, and  $s_{\text{eff}}$ ,  $f$  and  $\xi$  are the so-called saturation, leakage and coupling factors, respectively. The maximal value of  $\xi$  is +0.5 for pure dipolar and –1 for pure scalar relaxation;  $f$  can reach unity at high radical concentrations (tens of mM). The effective saturation factor of

the polarizer describes the deviation of electron spin polarization  $\langle S_Z \rangle$  from Boltzmann equilibrium  $S_0$ , i.e.  $s_{\text{eff}} = (S_0 - \langle S_Z \rangle)/S_0$ , and accounts for contribution of all hyperfine lines.<sup>6</sup> In standard DNP, this deviation is achieved by saturating the EPR line with on-resonant MW irradiation, i.e.  $s_{\text{eff}} \rightarrow 1$  for  $\langle S_Z \rangle \rightarrow 0$ . On the other hand, a saturation factor  $|s_{\text{eff}}| > 1$  can be in principle achieved if the electron spin system is driven above thermal equilibrium, for instance, by optical excitation. Replacement of MW with optical irradiation could potentially alleviate issues of MW absorption in liquids, particularly at high MW frequencies.<sup>7</sup> Optically-driven DNP (ODNP) has been demonstrated in the solid state, where  $^1\text{H}$  enhancements  $> 10^4$  have been observed using photo-excited triplet states of aromatic molecules.<sup>8–10</sup> However, the polarization of triplet states is orientation dependent and is reduced by fast molecular rotation.<sup>11</sup> On the other hand, triplet states in solution can polarize nearby radicals.<sup>12</sup> Indeed, nitroxide radicals can be optically polarized if mixed<sup>13</sup> with or covalently linked to dyes.<sup>14,15</sup> Recently, ODNP was reported in solution using a mixture of Rose-Bengal and TEMPO.<sup>16</sup> In a radical/dye mixture the mechanisms of both radical polarization and Overhauser DNP are dependent on the correlation times of molecular motion. We propose here a different approach, for which the radical is chemically linked to the dye at a fixed distance. In this case, the mechanism of radical polarization depends on the radical–triplet exchange interaction dictated by the linker.<sup>17</sup>

Recently, we have reported a series of functionalized nitroxides composed of a fullerene ( $\text{C}_{60}$ ) moiety, a pyrrolidine linkage and a TEMPO (2,2,6,6-tetramethylpiperidine-1-oxyl) radical (Scheme 1A) as new potential polarizers for liquid DNP.<sup>18</sup> In addition, side chains were introduced into the fullerene cage to

**Scheme 1** (A) Scheme of the FN ( $n = 0$ ) structure and its derivatives FN-1a and FN-2a ( $n = 1, 2$ ) with different numbers of adducts ( $R$ ). (B) Simplified energy level scheme and transitions of FN after laser excitation according to Corvaja & coworkers.<sup>22</sup>

increase their rotational and diffusional correlation time as well as solubility in water.<sup>19</sup> The compounds revealed an improved saturation factor for MW-driven DNP while the coupling factor in toluene was found to be comparable to that of the common polarizer TEMPONE (4-oxo-2,2,6,6-tetramethylpiperidine 1-oxyl).<sup>20</sup> Besides, the photo-excited state properties of fullerene–nitroxide (FN) have been extensively investigated by Corvaja and coworkers.<sup>17,21–23</sup> Scheme 1B illustrates a simplified electronic-state diagram of photo-excited FN.<sup>22</sup> The  $C_{60}$  and nitroxide moieties of FN can be considered as two separate electronic entities with electronic excitation localized on the fullerene. The ground state is a doublet ( $S = 1/2$ ) and denoted as  $D_{S0}$ , where the subscript indicates the electronic excitation on  $C_{60}$ . Immediately after photo-excitation of  $C_{60}$  to its first excited singlet state  $S_1$ , the total electronic state is  $D_{S1}$ . Intersystem crossing into the  $^3C_{60}$  and exchange coupling of this  $S = 1$  state with the radical  $S = 1/2$  state lead to an excited  $D_{T1}$  doublet and a  $Q_{T1}$  quartet state. The exchange interaction was determined to be positive and places  $D_{T1}$  at a higher energy with respect to  $Q_{T1}$ .<sup>22</sup>

In this paper, we report continuous wave (CW) transient EPR, pulsed EPR and DNP using FN and its derivatives (FN-1a and FN-2a) under light illumination. We show that increasing the size of the polarizing agent has a systematic effect on spin dynamics. Furthermore, we report our first observation of solution DNP by pumping fullerene nitroxide derivatives with CW laser excitation. The results provide a frame to optimize the performance of polarizers for ODNP and pave the way for more systematic investigations.

## Experimental methods

### Sample preparation

The synthesis of fullerene–nitroxide (FN) derivatives was described in our previous report.<sup>18</sup> To prepare the sample for EPR and DNP studies, a desired amount of a particular FN derivative was dissolved in toluene (99.9%, ACS grade, Merck KGaA, Germany) and loaded to either a 1.6 mm O.D. (1.1 mm I.D., volume 10  $\mu\text{l}$ ) or a 4 mm O.D. (3 mm I.D., volume 20  $\mu\text{l}$ ) quartz tube. Oxygen was removed by five freeze–pump–thaw cycles. The final pressure in the tube was

approximately  $1 \times 10^{-5}$  mbar. The tube was then sealed. During sealing the sample was kept frozen in liquid nitrogen. The sample concentration was determined by double-integration of the X-band CW EPR spectrum and by comparing the integrated intensity with a series of samples with known spin concentration.

### CW transient and pulse EPR at the X-band with laser excitation

CW transient EPR was conducted using a Bruker ElexSys E500 CW/transient EPR spectrometer equipped with a Bruker FlexLine dielectric microwave resonator (EN 4118X-MD4). The resonator holds a rectangular (10  $\times$  3 mm) window, containing a wire grid (0.1 mm wire width, 0.5 mm spacing between wires), which allows for optical illumination of the samples. A LeCroy oscilloscope (WaveJet 354, 500 MHz) and a Philips pulse generator (PM 5786) were used to synchronize the EPR signal detection with laser pulse excitation. Nitrogen gas flow was purged into the cavity during measurements.

Pulsed EPR experiments were performed using a commercial Bruker ElexSys E580 spectrometer equipped with a 1 KW TWT MW amplifier (Applied Systems Engineering) and an EN4118X-MD4 Bruker resonator. For FID detection the resonator was overcoupled and the length of a  $\pi/2$  microwave pulse was approximately 20 ns.

Photoexcitation was performed using a Nd:YAG pulsed laser (Surelite™ SLI-20 Continuum, 20 Hz repetition rate). The FWHM of a laser pulse is specified to be around 6 ns. After a 124  $\mu\text{s}$  Q-switch delay, the average laser power at 532 nm is around 80 mW ( $\approx 4$  mJ per pulse), which was measured using a thermopile power meter (LabMax™-TO, Coherent).

### X band (0.34 T) DNP and 14 MHz $^1\text{H-NMR}$ signal detection

Samples were inserted into a Bruker X-band ENDOR resonator (EN 4118X-MD4) and the magnetic field was supplied using a Bruker ElexSys E500 spectrometer.  $^1\text{H-NMR}$  signals were measured using a Bruker AVANCE III spectrometer. A matching circuit was connected to the ENDOR resonator to tune the NMR circuit at a  $^1\text{H}$  resonance around 14.6 MHz. Nitrogen gas was purged into the resonator to prevent sample overheating. A 445 nm laser (Laserworld BLUE-4500/445) was used as a CW laser illumination source. A mechanical shutter (SH05 and controller SC10, Thorlab) was controlled using a delay generator to set a suitable illumination time. The Bruker AVANCE console was employed to trigger the delay generator, the timing of the radio frequency (RF) pulse and NMR-FID detection. The length of the RF pulse was set to 3  $\mu\text{s}$ . Signal intensities were defined as the magnitudes calculated from the real and imaginary signal components. The delay time between each scan was set to about 2 minutes to avoid sample overheating. The uncertainty of the enhancement is about 10% and was determined by measuring on three different samples with the same concentration.

## Results and discussion

### CW-transient and pulse EPR of photoexcited FNs

To examine the capability of the FNs to act as a polarizer for liquid DNP, we first examined the polarization of nitroxide

**Fig. 1** X-band (9.8 GHz) CW transient EPR spectra of 1.5 mM **FN** (red) and **FN-2a** (black) in toluene recorded 2.5  $\mu$ s (solid trace) and 4.1  $\mu$ s (dash trace) after pulse laser excitation. Transitions assigned to the  $D_{S_0}$  and  $Q_{T_1}$  states are marked.

radicals in their photoexcited states. Fig. 1 illustrates representative spin polarized CW-transient EPR spectra (X-band/0.34 Tesla) of **FN** in solution at room temperature as compared to its derivative **FN-2a** after pulse irradiation with a 532 nm Nd:YAG laser. Consistent with ref. 17 and 21, for **FN** we observe signatures of a polarized nitroxide radical  $S = 1/2$  corresponding to the  $D_{S_0}$  state and of the photo-excited  $Q_{T_1}$  state.<sup>17,21,23,24</sup>

These two components can be distinguished according to their  $g$ -factors and nitroxide hyperfine splittings and are also observed here in **FN-1a** and **FN-2a** (Fig. 1 and Fig. S1, ESI<sup>†</sup>), albeit with different time evolutions of polarization profiles. The  $g$ -factor and hyperfine splitting of  $Q_{T_1}$ ,  $g_{QT}$  and  $A_{QT}$ , are  $g_{QT} = 1/3g_R + 2/3g_T$  and  $A_{QT} = 1/3A_R$ , where  $g_R = 2.006$  and  $A_R = 15.35$  G are the isotropic  $g$ -factor and the hyperfine splitting of the nitroxide radical, and  $g_T = 2.0014$  is the isotropic  $g$ -factor of the  $C_{60}$  triplet state.<sup>25,26</sup> The solution-state EPR resonance of  $^3C_{60}$  is displayed in Fig. S2 (ESI<sup>†</sup>) for comparison.

The time evolution of the CW transient EPR signals of  $D_{S_0}$  and  $Q_{T_1}$  at selected magnetic field positions is displayed in Fig. 2A. As the concentration of the nitroxide radicals remains constant during the experiment, it is clear from Fig. 2A that light illumination drives the ground state  $D_{S_0}$  nitroxide polarization ( $P \propto \langle S_z \rangle$ ) of the **FNs** away from thermal equilibrium. However, to our knowledge, all studies performed using CW transient EPR spectroscopy did not report a direct determination of this transient polarization. The reason for this is that this method detects only changes in signal intensities and is blind toward time-independent signals.<sup>27</sup> To obtain more quantitative information, we repeated the experiment as shown in Fig. 2A using pulsed EPR, which allows for a direct comparison of a polarized signal with a reference Boltzmann signal (Fig. 2B). Moreover, the analysis of transient pulsed EPR signals

**Fig. 2** (A) Time evolutions of the CW transient X-band (9.8 GHz) EPR signals of **FN** (1), **FN-1a** (2) and **FN-2a** (3) after laser pulse at 532 nm. Red and blue traces are the  $D_{S_0}$  state detected at the low-field hyperfine line and  $Q_{T_1}$  detected at the central hyperfine line, respectively. Black traces are the bi-exponential fits; the rates are shown in Fig. 3. The field-dependent spectra are shown in Fig. S2 (ESI<sup>†</sup>). (B) Normalized FID intensities ( $I_{exc}/I_0$ ) of 0.8 mM (1) **FN**, (2) **FN-1a** and (3) **FN-2a** in toluene (20  $\mu$ l) as a function of the delay time after a laser pulse of 4 mJ energy. Red and black traces are FID intensities with or without laser pulse, respectively. Blue traces are fits with two exponential decays. Time constants are summarized in Fig. 3. Inset: Pulse sequences.  $\nu_{MW} = 9.8$  GHz; shot rep. time: 20 ms; FID signals were collected at the low-field hyperfine nitroxide transition of the  $D_{S_0}$  state (see Fig. 1) after a dead time of 200 ns from the MW pulse.

is more straightforward as detection is accomplished in the absence of MW irradiation. Fig. 2B displays the FID-detected time evolution of the nitroxide low-field hyperfine line in the  $D_{S0}$  state as compared to the initial Boltzmann signal ( $t < 0$  and transients without a laser pulse). In all compounds, the time evolution of the polarization is very similar to that observed in CW transient EPR (Fig. 2A) and consists of three components: (1) a fast initial emission, (2) signal inversion emission-to-absorption and (3) a decay. According to the analysis of ref. 21, these changes of radical polarization in the  $D_{S0}$  state are due to the so-called reversed-quartet mechanism RQM, a process by which reverse intersystem crossing between  $Q_{T1}$  and  $D_{T1}$  is fully competitive with the decay of these states to the ground state  $D_{S0}$  and to spin lattice relaxation back to a Boltzmann distribution (see also Section Kinetics and radical polarization).

The data in Fig. 2B show that at the time point of the maximal, absorptive FID signal the nitroxide FID reaches an intensity ( $I_{\max}$ ) of about 4-fold (FN and FN-1a) to 3-fold (FN-2a) the Boltzmann equilibrium value ( $I_0$ ). The detected signal is proportional to the sample magnetization  $M = c \cdot P$ , where  $c$  is the spin concentration and  $P$  is the polarization defined here as magnetization per unit volume and spin.  $P$  is in turn proportional to  $\langle S_z \rangle$  and thus to the difference in population of the detected transition.<sup>28</sup> If all molecules were photo-excited (excitation efficiency  $\alpha = 1$ ), the maximal transient polarization  $P_{\max}$  from Fig. 2B would be  $4 \cdot P_0$  (for FN and FN-1a) and  $3 \cdot P_0$  for FN-2a, where  $P_0$  is the Boltzmann equilibrium value. However, the excitation efficiency is usually much less than 1 and the detected signal results to:

$$\frac{I_{\max}}{I_0} = \frac{\alpha \cdot P_{\max} + (1 - \alpha) \cdot P_0}{P_0} \quad (2)$$

Therefore, an estimate of  $P_{\max}/P_0$  requires knowledge of  $\alpha$ , which depends on the optical extinction coefficient as well as on the illumination setup.  $\alpha$  is defined as the ratio between the number of excited molecules ( $N_{\text{exc}}$ ) and the total number of molecules ( $N_0$ ). In the literature  $\alpha$  is usually estimated theoretically, but in practice the uncertainty due to laser power losses might be quite large, particularly if the sample resides in an EPR cavity. To estimate  $\alpha$  for FN we used calibration with the EPR signal of  $^3\text{C}_{60}$  as a reference.

### Estimate of FN polarization using $^3\text{C}_{60}$

We know from previous studies that the transient  $^3\text{C}_{60}$  signal in solution is proportional to its thermal equilibrium polarization (Fig. S4, ESI<sup>†</sup>).<sup>12,29</sup> Thus  $\alpha(^3\text{C}_{60})$  can be determined by comparing the FID intensity of the  $^3\text{C}_{60}$  triplet state signal in solution with a reference signal, for instance here 4-oxo-TEMPO- $d_{16}$ - $^{15}\text{N}$ .

$^3\text{C}_{60}$  in solution consists of a single narrow EPR line with an electron spin-spin relaxation time ( $T_2 \approx 450$  ns)<sup>29</sup> that permits FID detection by pulse EPR at room temperature. The  $^3\text{C}_{60}$  signal after a laser pulse was detected by integrating the FID over a short time window ( $< 10$  ns) right after the spectrometer detection dead time ( $t_{\text{dead}}$ , Fig. S4 (ESI<sup>†</sup>)). The delay time between the laser pulse and the microwave detection pulse was incremented in 20 ns steps. According to the experiments

and analysis in ref. 12 and 30,  $^3\text{C}_{60}$  shows no detectable magnetization immediately after light excitation. Because of the fast rotation in solution, both triplet state EPR transitions collapse within the same resonance line and the observed build-up signal is due to spin-lattice relaxation ( $T_1$ ), with the maximum signal corresponding to the triplet Boltzmann magnetization. Therefore, the intensity of this maximal signal, if calibrated against the Boltzmann signal of reference samples with known concentration, can be used to estimate the number of photo-excited  $^3\text{C}_{60}$  molecules.

Under the same experimental conditions, the Boltzmann FID signal of a  $^{15}\text{N}$ -labeled nitroxide radical (4-oxo-TEMPO- $d_{16}$ - $^{15}\text{N}$ ) and the Boltzmann FID signal of  $^3\text{C}_{60}$  are proportional to the spin concentration  $c$  and their respective Boltzmann polarisation  $P_0$ , i.e.  $I_{\text{FID}} \propto c \cdot P_0$ , with the same proportionality constant. For  $^3\text{C}_{60}$  the concentration  $c$  of the molecules in their triplet state depends on  $\alpha$ , i.e.  $c(^3\text{C}_{60}) = \alpha \cdot c(\text{C}_{60})$ . The FID intensities of  $^3\text{C}_{60}$  and  $^{15}\text{N}$  nitroxide in Boltzmann equilibrium can be compared as

$$\frac{I(\text{NO})}{I(^3\text{C}_{60})} = \frac{I^{\text{det}}(\text{NO}) \cdot e^{-\frac{t_{\text{dead}}}{T_{2,\text{NO}}}}}{I^{\text{det}}(^3\text{C}_{60}) \cdot e^{-\frac{t_{\text{dead}}}{T_{2,^3\text{C}_{60}}}}} = \frac{\frac{1}{2}c(\text{NO})P_0(\text{NO})}{\alpha(^3\text{C}_{60})c(\text{C}_{60})P_0(^3\text{C}_{60})} \quad (3)$$

Here  $I^{\text{det}}(\text{NO})$  and  $I^{\text{det}}(^3\text{C}_{60})$  are the detected transient FID signals after a  $\pi/2$  mw pulse and the detection dead time.  $T_{2,\text{NO}}$  and  $T_{2,^3\text{C}_{60}}$  are the spin-spin relaxation times of  $^{15}\text{N}$  nitroxide and  $^3\text{C}_{60}$ , respectively. The factor 1/2 takes into account that only one of the two  $^{15}\text{N}$  nitroxide hyperfine lines is detected.  $P_0$  is defined here as the equilibrium magnetization per unit volume and spin:<sup>12</sup>

$$P_0 = \frac{\hbar^2 \gamma^2}{3kT} BS(S+1) \quad (4)$$

where  $S$  is the spin quantum number,  $\hbar$  and  $\gamma$  are the Planck constant and the gyromagnetic ratio respectively,  $k$  and  $T$  are the Boltzmann constant and temperature (we note the slightly different definition of  $P$  with respect to the DNP literature, in which 'polarization' refers to population differences and not to magnetization). Using eqn (4) the equilibrium polarization of a spin system with  $S = 1$  is equal to 8/3 of the equilibrium polarization in a spin system with  $S = 1/2$ . Inserting this relation into eqn (3), the excitation efficiency for  $^3\text{C}_{60}$  results to:

$$\alpha(^3\text{C}_{60}) = \frac{3}{16} \frac{c(\text{NO})I(^3\text{C}_{60})}{c(\text{C}_{60})I(\text{NO})} \quad (5)$$

For this purpose, a calibration curve of the  $^{15}\text{N}$  nitroxide FID signal (recorded at the low-field EPR line) was measured, and  $\alpha(^3\text{C}_{60})$  was extracted from eqn (5) for different concentrations of  $\text{C}_{60}$ , as shown in Tables S3 and S4 (ESI<sup>†</sup>). We obtain  $\alpha(^3\text{C}_{60})$  on the order of 0.05–0.1, depending on the considered sample concentration. For comparison, the calculated value while taking into account our laser parameters (laser pulse length and energy, beam spot area, absorption cross section and quantum yield of  $^3\text{C}_{60}$ ) amounts to  $\approx 0.15$  (see S13, ESI<sup>†</sup>). Obviously, the latter value does not include losses through the optical path.

Finally, the excitation efficiency of **FN** can be estimated by a comparison to  $\alpha(^3C_{60})$  under the same experimental conditions (according to eqn (1) of SI3, ESI<sup>†</sup>):

$$\frac{\alpha(\mathbf{FN})}{\alpha(^3C_{60})} \approx \frac{\varepsilon(\mathbf{FN}) Y(\mathbf{FN})}{\varepsilon(^3C_{60}) Y(^3C_{60})} \quad (6)$$

where  $\varepsilon$  is the respective extinction coefficient. From a previous report, the quantum yield of the **FN** excited triplet state  $Y(\mathbf{FN})$  is 0.93.<sup>31</sup> The corresponding extinction coefficients at 532 nm are obtained from Tables S1 and S2 (ESI<sup>†</sup>) ( $\varepsilon_{532}(\mathbf{FN}) = 1200 \text{ M}^{-1} \text{ cm}^{-1}$  and  $\varepsilon_{532}(C_{60}) = 900 \text{ M}^{-1} \text{ cm}^{-1}$ ). If we use  $\alpha(^3C_{60}) \approx 0.05\text{--}0.1$  from Table S3 (ESI<sup>†</sup>),  $\alpha(\mathbf{FN})$  is in the range of 0.06–0.12. Using the ratio of the FID signals  $I_{\text{max}}/I_0$  in eqn (2) we arrive to a maximal, positive photo-induced radical polarization for **FN** of  $P_{\text{max}}/P_0 \approx 30$ . The spread of values accounting for the concentration effects and errors is at least  $\pm 30\%$ . Unfortunately, we cannot carry out the same estimate for **FN-1a** and **FN-2a** as we lack direct information on their triplet quantum yields. Literature values for bis-adducts indicate a decrease in quantum yield up to a factor of two,<sup>31</sup> however the extinction coefficients of **FN-1a** and **FN-2a** increase (Table S2, ESI<sup>†</sup>). Therefore  $P_{\text{max}}/P_0$  in the **FN** derivatives should also be one order of magnitude over Boltzmann equilibrium. This enhanced radical polarization can be used to induce DNP in liquids under steady-state continuous illumination, as we will show in the following.

### Kinetics of radical polarization

From the transient signals in Fig. 2 we note that the molecular size has an effect on kinetics. The build-up of the  $Q_{T1}$  and  $D_{S0}$  EPR signals and their decay become systematically slower from **FN** to **FN-2a**. We expect that the lifetime of radical polarization has an impact on steady-state polarization required for DNP; therefore we examined the polarization decays in more detail. The kinetics for the formation and decay of the spin-polarized states  $Q_{T1}$  and  $D_{S0}$  is a complex mix of population changes between the spin-sublevels due to exchange coupling of the  $D_{T1}$  and  $Q_{T1}$  states and due to spin lattice relaxation. Corvaja *et al.* treated this problem using a rate equation approach including kinetic terms connecting the spin sublevels of  $D_{T1}$ ,  $D_{Q1}$  and  $D_{S0}$ . This model leads to a complex series of equations with rate constant that are not readily accessible. A later work by Wasielewski *et al.*<sup>32</sup> corroborated a semi-quantitative description of the RQM kinetics. Within this model the initial fast emissive polarization of  $Q_{T1}$  arises from a fast spin selective decay of  $D_{T1}$  ( $|(-1/2)\rangle$ ) to the  $Q_{T1}$  ( $|(3/2)\rangle$ ) spin state, as these two levels have the smallest energy gap (Scheme 1). Optical data indicated that the decay of  $Q_{T1}$  matches the emissive built up of  $D_{S0}$ .<sup>32</sup> A subsequent RQM mechanism leads to a slower polarization inversion (emission-to-absorption) and slower decays to Boltzmann equilibrium.

As the initial signal emission is fast as compared to the time scale of our experiments, we considered only the kinetics of polarization inversion and decay. For comparison, we fitted the kinetics of the pulsed and the CW transient EPR signals. We note that the CW transient EPR spectra (Fig. 2A), which were measured at low MW power (here  $\omega_1/2\pi \approx 0.2 \text{ MHz}$ ) and

Fig. 3 Summary of fitted time constants for polarization build-up and decay of  $D_{S0}$  and the  $Q_{T1}$  states as a function of the rotational correlation times ( $\tau_c$ )<sup>18</sup> for the three different **FNs**. Plotted are decay rates of  $D_{S0}$  as compared to the spin lattice relaxations from ref. 18 and build-up rates of  $D_{S0}$  as compared to the decay rate of  $Q_{T1}$ .

in on-resonance EPR fields, are proportional to the difference in the populations of the detected transitions, as illustrated by Corvaja *et al.*<sup>17</sup>

The curves in Fig. 2 were fitted using a simple bi-exponential function, which reproduces the effective kinetics of the population difference in the  $D_{S0}$   $S = 1/2$  spin state (we recall that the radical concentration is constant). The fits are displayed in Fig. 2 superimposed to the data. The rates obtained from both FID and CW transient EPR were quite similar, and are plotted in Fig. 3. As a major result we found that the time constants for the radical polarization decay  $\tau_{D_{S0},\text{decay}}$  are consistent – within the error – with the radical  $T_{1e}$  measured by saturation recovery ELDOR.<sup>18</sup> Deviations might be due to small differences in temperature or concentrations due to different experimental conditions. The observation of a  $T_{1e}$ -limited polarization lifetime of  $D_{S0}$  is consistent with the fact that the polarization of the excited  $Q_{T1}$  state decays faster and rather matches the  $D_{S0}$  build up constant (Fig. 2A), supporting the RQM mechanism proposed by Corvaja *et al.*<sup>22</sup> We note that the present data on **FN-1a** and **FN-2a** illustrate this trend even more clearly than those on **FN** because of the slower kinetics. Overall, the decay time constant  $\tau_{D_{S0},\text{decay}}$  of radical polarization increases with the size of the molecule, according to an increasing rotational correlation time  $\tau_c$  and  $T_{1e}$ .<sup>18</sup>

### Optically-driven DNP

Finally, we examined whether the photo-induced polarization of the nitroxide radical can be transferred to the protons of the toluene solvent using steady-state illumination with a 3 W CW laser at 445 nm. For this purpose, the <sup>1</sup>H-NMR signals of toluene at different concentrations of **FN** derivatives with/without illumination were measured. Fig. 4 collects the <sup>1</sup>H-NMR signal enhancements of toluene at 0.34 Tesla after a laser illumination of 3–5 s, depending on the sample size and concentration. Representative time-domain NMR data for **FN-1a** are shown in Fig. S5 (ESI<sup>†</sup>). Although the enhancements are small ( $\varepsilon = I/I_0 \leq 1.5$ ), several observations indicate that the DNP effect follows the

Fig. 4  $^1\text{H-NMR}$  signal enhancements of toluene doped with **FN** (black), **FN-1a** (red) or **FN-2a** (blue) in a 4 mm O.D. quartz tube (volume 20  $\mu\text{l}$ ) at different concentrations, illuminated to a 3 W 445 nm laser for 5 s. The unfilled red and blue squares are samples in a reduced volume of 10  $\mu\text{l}$  (1.1 mm O.D. tubes), exposed for 3 s. The inset shows the  $^1\text{H-NMR}$  spectrum of toluene mixed with 0.8 mM **FN-1a** with (red) and without laser (black), respectively. The two peaks are contributed by methyl and ring protons, respectively.

expected behaviour from the Overhauser mechanism eqn (1) and are correlated with the polarization profiles shown in Fig. 2. The observed DNP enhancements of toluene are positive, in contrast to the common expectation from dipolar relaxation with a positive coupling factor. Indeed, according to Fig. 2, the long-lived positive radical polarization  $P_{\text{exc}} > P_0$  gives rise to a negative DNP saturation factor  $s_{\text{eff}} = (S_0 - \langle S_z \rangle) / S_0$ . Thus, the resulting sign of the enhancement in eqn (1) must be positive. We also observe a pronounced concentration dependence, with an optimal concentration around 1.5 mM, likely due to deactivation of the excited states at concentrations  $\geq 1$  mM.<sup>29</sup> We note that we do not observe a DNP enhancement with **FN**. The build-up curve of the DNP enhancements is shown in Fig. 5.

Fig. 5 Build-up of  $^1\text{H-NMR}$  signal enhancements of toluene doped with 0.8 mM **FN-1a** at different laser (2.8 W) illumination periods. The red trace is the fitted curve with a build-up time  $T_{\text{build-up}} = 1.6 \pm 0.4$  s. The  $T_{1n}$  for **FN-1a** is  $3.2 \pm 0.3$  s, the difference between  $T_{1n}$  and  $T_{\text{build-up}}$  is likely due to the heating effects.

Importantly, it follows expected kinetics according to  $T_{1n}$  that is on the time scale of seconds.<sup>33</sup>

Our DNP results appear to be consistent with the previous report of a photo-induced  $^1\text{H-NMR}$  DNP signal up to  $-4$  of water in a mixture of Rose-Bengal and TEMPO.<sup>16</sup> As compared to our enhancements, the reported larger negative enhancement is consistent with the completely emissive (negative) transient polarization of TEMPO mixed with Rose-Bengal.<sup>13</sup> The occurrence of emission and absorption in the traces of **FN-1a** and **FN-2a** (Fig. 2) might attenuate the steady-state total polarization and seems to be a disadvantage. Moreover, the photo-excited polarization of Rose-Bengal was estimated to be  $P_{\text{max}}/P_0 \approx -150$ ,<sup>13</sup> which is one order of magnitude larger than our estimate for the **FN** derivatives. On the other hand, Rose-Bengal is unstable under light excitation and the experiments in ref. 16 were performed under flow-conditions,<sup>16</sup> whereas we observed no degradation of the polarizers over several cycles. Another interesting observation is the absence of photo-induced DNP with **FN** (Fig. 4), which – at this stage – can be only rationalized by a shorter lifetime of photo-induced radical polarization (Fig. 3).

## Conclusions

All these considerations and the comparison with the Rose-Bengal/nitroxide system shed light on some key parameters to optimize optically-driven liquid DNP. These are the excitation efficiency of the dye, the photo-excited polarization of the radical, its time evolution and lifetime. The stability of the dye is also a critical aspect. It might be possible to improve the performance of the polarizers through rational molecular design; however, the complexity of the whole mechanism still demands an experimental approach based on systematic dye-polarizer screening. The successful optically-driven DNP experiments suggest that this method could potentially become an attractive way to enhance NMR in a liquid state.

## Conflicts of interest

The authors declare that there are no conflicts of interest.

## Acknowledgements

We thank Dr. Vladimir Belov, Jürgen Bienert, Jens Schimpfhauser and Jan Seikowski from MPIBPC Chemical Synthesis facility for synthesizing fullerene nitroxide and its derivative. This work was funded by the Max Planck Society and the COST Action TD1103 (European Network on Hyperpolarization). G. L. thanks the Alexander von Humboldt Foundation for a fellowship. N. E. acknowledges the Graduate School for Neurosciences, Biophysics and Molecular Biosciences in Göttingen (GGNB) for financial support. Open Access funding provided by the Max Planck Society.
