Evaluation of different metal salt solutions for the preparation of solar cells with wide-gap $\text{Cu}_2\text{ZnGeS}_x\text{Se}_{4-x}$ absorbers†

T. Schnabel,* M. Seboui and E. Ahlswede

In this work, thin-film solar cells with a kesterite-type $\text{Cu}_2\text{ZnGeS}_x\text{Se}_{4-x}$ (CZGSSe) absorber were prepared from four different metal salt solutions. Their high band gap makes them an interesting material for tandem solar cells. The structural and morphological properties of the absorbers are compared with an additional focus on the electrical properties of the resulting thin-film solar cells. Efficiencies exceeding 5% could be demonstrated.

Introduction

In recent years the kesterite-type material $\text{Cu}_2\text{ZnSnS}_x\text{Se}_{4-x}$ (CZTS) has gained particular attention as an absorber material for thin-film solar cells. It offers a tunable band gap between 1.0 and 1.5 eV that can be adjusted *via* the S/Se-ratio. However, if one wants to use a kesterite material as a top cell in tandem solar cells, this range of band gaps is still too low. Therefore a different approach is necessary to further increase the band gap.

One possibility is the replacement of tin by germanium, which has a smaller ionic radius and can increase the band gap to values between 1.4 eV ($\text{Cu}_2\text{ZnGeSe}_4$, CZGSe¹) and 2.0 eV ($\text{Cu}_2\text{ZnGeS}_4$, CZGS²). However, for solar cells with kesterite-type absorber Ge is mostly used only as a dopant in small quantities.³ Additionally, there are some reports about mixed $\text{Cu}_2\text{-ZnSn}_{1-y}\text{Ge}_y\text{S}_x\text{Se}_{4-x}$ absorbers.⁴⁻⁶ Here the best results were obtained for *y*-values between 0.25 and 0.4 with efficiencies approaching or exceeding 10%.^{4,7,8} In these reports the efficiencies are strongly declining for *y* > 0.5 and no explicit values for pure $\text{Cu}_2\text{ZnGeS}_x\text{Se}_{4-x}$ (CZGSSe) have been reported. In addition, there are a few manuscripts that mostly focus on structural and optical properties of CZGSSe,^{1,9} one of them showing a *J-V*-characteristic with a diode-shape, but no solar cell parameters.¹⁰ For solar cells based on CZGS monograins an efficiency of 1.3% was achieved by Timmo *et al.*,¹¹ which is the highest reported efficiency so far.

Solution-based approaches allow both simple process technologies and low deposition costs and are interestingly head-on with vacuum-based approaches in the case of kesterite solar cells.¹² Hence, the scope of this manuscript is to investigate

different metal salt solutions for the synthesis of CZGSSe absorbers. Their optical and morphological properties are discussed with a focus on their suitability for the use in thin-film solar cells, resulting in the highest reported power conversion efficiency for this material.

Experimental

In this work four different metal salt solutions are compared. All of them were prepared with stoichiometries of $\text{Cu}/(\text{Zn} + \text{Ge}) = 0.7$ and $\text{Zn}/\text{Ge} = 1.0$, thus after a slight Ge-loss during annealing being in the Cu-poor and Zn-rich regime that has proven to be favourable for CZTS. The choice of solvent is motivated by both a good solubility of various metal salts and ideally by only little environmental impact: dimethyl sulfoxide (DMSO) – an established solvent for CZTS,¹³ *N,N*-dimethylformamide (DMF) as rather new candidate, and finally water. For solution A, copper(i)-acetate (0.45 M), zinc(ii)-chloride (0.31 M), germanium(iv)-chloride (0.31 M) and thiourea (1.45 M) have been dissolved in DMSO. A turbid suspension is formed. The EDX-analysis of the precipitate showed S, O and Ge in different amounts. Solution B also has DMSO as solvent with copper(ii)-acetate (0.44 M), zinc(ii)-chloride (0.30 M) and germanium(iv)-iodide (0.30 M) as metal salts and thiourea (1.41 M) as sulfur-source.¹⁴ It forms a deep-red solution, which is clear when freshly prepared, but forms some precipitate over time. Solution C is prepared from copper(ii)-oxide (0.31 M), zinc(ii)-oxide (0.21 M) and germanium(iv)-oxide (0.21 M) that are solved in an aqueous solution of ammonium thioglycolate (ATG, 1.67 M). A clear, yellow solution is formed.¹⁵ Note that the solutions B and C are not prepared with Cu in the proper oxidation state for the kesterite lattice, which is +1. However, Cu(i) is formed through a redox reaction. Solution D consists of copper(i)-chloride (0.46 M), zinc(ii)-chloride (0.32 M), germanium(iv)-chloride (0.31 M) and thiourea (1.48 M) that are dissolved in DMF and form a clear, yellow solution.⁴ A picture of all four solutions is displayed in Fig. 1.

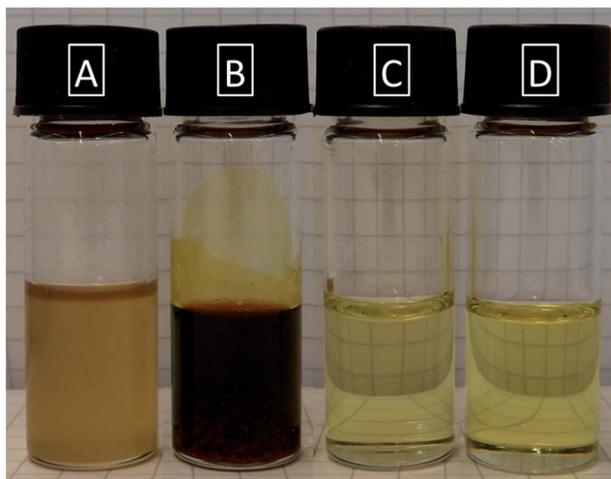

Fig. 1 Picture of the metal salt solutions A–D.

The metal salt solutions are deposited onto a Mo/soda lime glass substrate by doctor-blade coating and a subsequent drying step on a hot plate. The film thickness can be adjusted by the number of subsequent coating steps. Afterwards, the sample is annealed at approximately 550 °C inside a graphite box in selenium-atmosphere. Additional experimental details can be found in ref. 16. To obtain functional solar cells, the samples are completed with a CdS-layer (50 nm) by chemical bath deposition and a sputtered intrinsic ZnO (40 nm) and an aluminium-doped ZnO (400 nm) layer and separated to single cells of 0.25 cm² each by mechanical scribing.

Current–voltage curves were measured using a Keithley 2400 source measuring unit under simulated AM 1.5 global solar irradiation with an WACOM 2-lamp sun simulator at 100 mW cm⁻². External quantum efficiency measurements were performed with a setup from Optosolar. The morphology was investigated with a scanning electron microscope (SEM, XL30 SFEF Sirion) from FEI Company, using a 5 kV acceleration voltage. The same instrument was also used for energy-dispersive X-ray (EDX) measurements. Raman spectra were obtained by using a WITec CRM 200 confocal Raman microscope with a 532 nm excitation wavelength and a spot size of approximately 1 μm. X-ray diffraction (XRD) measurements were performed with the model Empyrean from Panalytical in Bragg–Brentano geometry.

Results

The morphologies of the samples from the metal salt solutions A–D are displayed in the SEM images in Fig. 2 and obviously show large differences. Sample A consists of small grains, only showing some larger crystals on the top and the bottom of the absorber. Additionally, an approximately 1 μm thick MoS_xSe_{2-x} layer is visible, which is of comparable thickness for all samples. Sample B is even more inhomogeneous than sample A, showing some crystals that are considerably larger than the thickness of the other samples with smaller grains in between, but no compact layer was formed. Sample C shows a more homogeneous morphology with a large-grain layer on top and

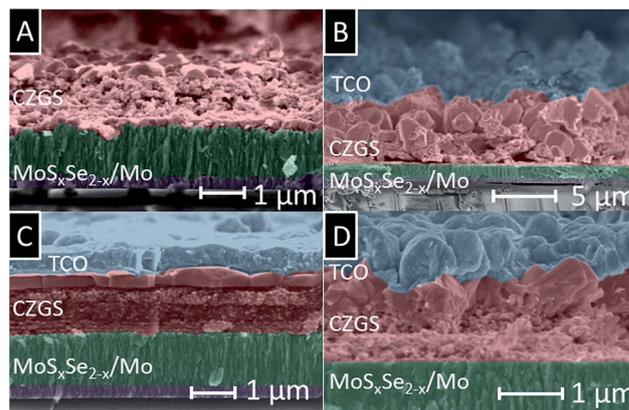

Fig. 2 Cross-section SEM images of absorbers prepared from the solutions A–D. The samples B–D are finished solar cells with buffer layer and TCO on top of the absorber. For the sake of clarity the layers are marked with different colors: blue for the TCO, red for the absorber, green for MoS_xSe_{2-x} and purple for Mo.

a thicker small-grain layer underneath. For sample D, a compact, but small-grain layer is visible with some larger grains on top.

The crystallinity of the absorbers is examined by XRD, as shown in Fig. 3. The reference card for CZGSe is added in black bars (JCPDS 052-0867). All absorbers appear to have the kesterite structure and no secondary phases are visible. The only reflexes not belonging to CZGSSe comply with Mo and MoSe₂. A more detailed plot of the 112- and the 202/204-reflex can be found in the ESI,[†] where a small amount of ZnSe was found for sample A. The reflexes are slightly shifted dependent on the S/(S + Se)-ratio, which can be estimated from the position of the 112-reflex *via* Vegard's law.^{17,18} This method shows that sample A has the lowest S/(S + Se)-ratio with 0.12 whereas especially the samples C and D have considerable S-incorporations with ratios around 0.3 (Table 1). These differences may be due to (i)

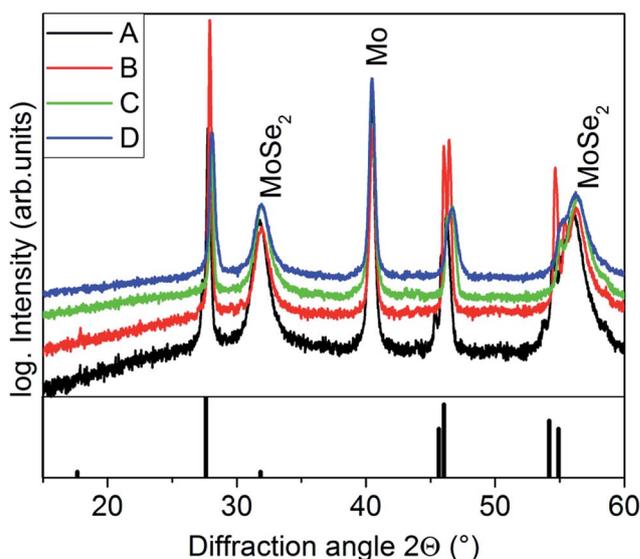

Fig. 3 XRD spectra of absorbers prepared from the solutions A–D and reference card JCPDS 052-0867 for CZGSe.

Table 1 Position of the 112-reflex, its FWHM and the S/(S + Se)-ratio that is determined via Vegard's law

| Sample | A (DMSO) | B (DMSO) | C (water) | D (DMF) |
|------------------|----------|----------|-----------|---------|
| 112-Position (°) | 27.799 | 27.914 | 28.043 | 28.095 |
| FWHM (°) | 0.267 | 0.164 | 0.267 | 0.361 |
| S/(S + Se) | 0.12 | 0.17 | 0.29 | 0.31 |

a different reactivity of the S-containing substances (thiourea vs. ATG) for forming $\text{Cu}_2\text{ZnGeS}_4$ in the precursor, or (ii) due to differences in the compactness of the absorber layers, leading to an enhanced replacement of S by Se during the annealing process for a less compact layer.

An indication for the crystal quality is the full width of half maximum (FWHM) of the XRD reflexes. Here sample B has with 0.164° by far the smallest value indicating larger crystals than for the other samples. This is in accordance with the SEM images shown in Fig. 2, where huge crystals can be found for sample B.

For additional investigations on the crystal structure Raman microscopy spectra are shown in Fig. 4. Here clear differences between the four absorbers are visible. First of all, all of them exhibit the A-modes for CZGSe at 205 and 177 cm^{-1} (ref. 19) and the A-mode for CZGS at 357 cm^{-1} (which is slightly red-shifted in comparison to the position observed by Guc *et al.* because of the high Se-content)²⁰ and therefore the kesterite-structure is confirmed. However, the latter mode is barely visible for the samples A and B, complying with their lower S/(S + Se)-ratios as determined by XRD. Weaker kesterite modes can be seen at 93 and $270\text{--}290\text{ cm}^{-1}$, which is in agreement with previous reports, too.^{11,19,20}

Interestingly, there is an additional mode at 223 cm^{-1} present for the samples C and D and as small shoulder for sample B; it varies in intensity (also on different spots on one

sample) and is the strongest mode for sample C, while its origin is not clear at the moment. It was not observed for CZGSe single crystals²¹ but for CZGSSe thin films by Khadka *et al.*²² which suggests that it might be a kesterite-mode dependent on the S/(S + Se)-ratio. In general it is observed that the Raman modes for the samples A and B are clearly sharper than those for the samples C and D. So if we combine the information from XRD and Raman, we can conclude that from a structural point of view sample B shows the best crystal quality, while the samples C and D have a higher S/(S + Se)-ratio. Both of them have also a strong contribution of the unknown Raman mode at 223 cm^{-1} .

A totally different picture can be drawn from the solar cell parameters of the solar cells made from samples A–D, which are shown as boxplots in Fig. 5. The corresponding maximum and average values can be found in Table 2, detailed J - V characteristics are displayed in the ESI.† It is obvious that sample D exhibits the highest values for all parameters and at the same time a smaller deviation than the samples A and C. Sample B is short-circuited due to the lack of a compact layer that gives access to many shunt paths and does therefore not exhibit any efficiency. For sample A the maximum efficiency η is 3.6%, but it is very inhomogeneous and therefore has an average value of only 0.9%. Its average efficiency and short-circuit current density (J_{sc}) are comparable to sample C. Although the latter is more homogeneous it only shows a maximum efficiency of 2.1% that might be limited by the high amount of carbon residues that comes from the used complexant ATG.²³ Due to the higher S/(S + Se)-ratio (see Table 1) the band gap of sample C (1.54 eV) is considerably larger.

Sample D is comparable to sample C in terms of band gap and S/(S + Se)-ratio. However, fill factor (FF), open-circuit voltage (V_{OC}), J_{sc} and therefore also the efficiency η are considerably higher reaching up to 5.1% with a V_{OC} of 615 mV, J_{sc} of 16.3 mA

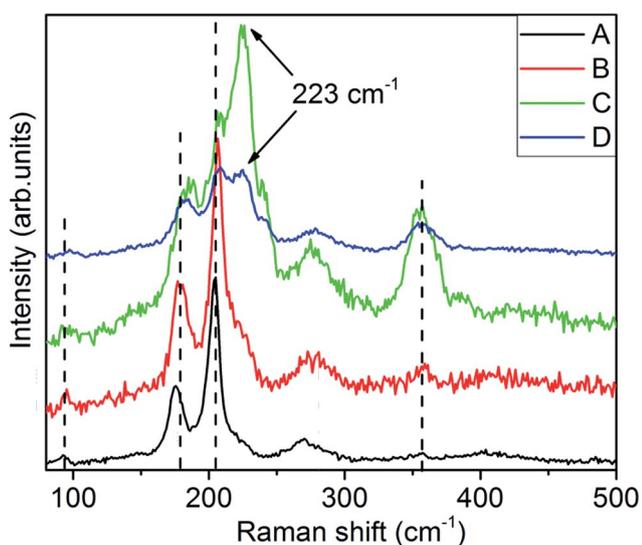

Fig. 4 Raman spectra of absorbers prepared from the solutions A–D measured with an excitation wavelength of 532 nm and a spot size of 1 μm . Expected Raman modes for CZGSe are indicated as dashed lines.

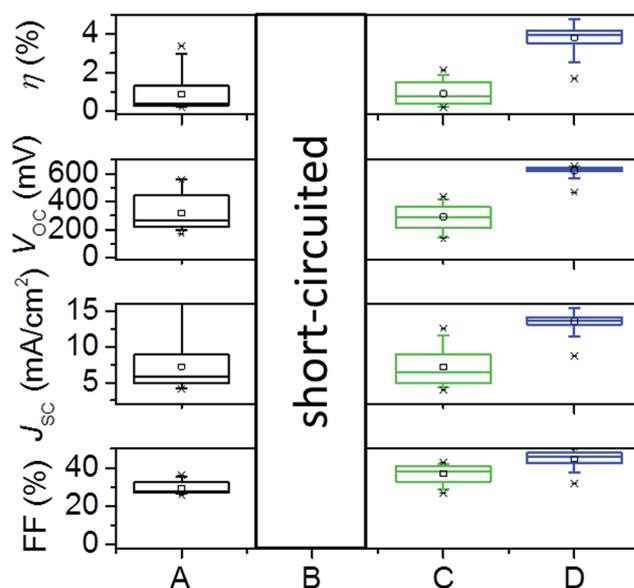

Fig. 5 Boxplots of the solar cell parameters η , V_{OC} , J_{sc} and FF for the samples A–D.

Table 2 Solar cell parameters of the best devices from samples A–D and the corresponding average values from more than 25 single cells. The band gap is estimated from EQE measurements, that are shown in the ESI

| | η_{\max} (%) | η_{av} (%) | $V_{\text{OC, max}}$ (mV) | $V_{\text{OC, av}}$ (mV) | $J_{\text{SC, max}}$ (mA cm ⁻²) | $J_{\text{SC, av}}$ (mA cm ⁻²) | FF _{max} (%) | FF _{av} (%) | E_{g} (eV) |
|-----------|-------------------|------------------------|---------------------------|--------------------------|---|--|-----------------------|----------------------|---------------------|
| A (DMSO) | 3.6 | 0.9 | 562 | 318 | 18.1 | 7.2 | 35.5 | 29.4 | 1.27 |
| B (DMSO) | N.A. | N.A. | N.A. | N.A. | N.A. | N.A. | N.A. | N.A. | N.A. |
| C (water) | 2.1 | 0.8 | 433 | 292 | 11.6 | 7.2 | 42.4 | 37.0 | 1.54 |
| D (DMF) | 5.1 | 3.8 | 615 | 621 | 16.3 | 13.6 | 50.7 | 44.6 | 1.50 |

cm⁻² and a FF of 50.7%. Note that the average V_{OC} of sample D is higher than the one of the best cell.

The differences between the four approaches in this manuscript in terms of efficiency cannot be explained by an isolated comparison of the used solvents. Instead, the combination of solvent, metal salts and sulfur-source has to be taken into account, which results in a complex interplay.

If one wants to judge on the solvent alone, the requirements for being a suitable solvent include *e.g.* (i) offering a high solubility for the used metal salts, (ii) not leaving any residues in the final absorber layer and (iii) having a sufficient wettability on Mo-substrates to obtain homogeneous layers.

With respect to these criteria, the solutions based on DMSO could not demonstrate their easiness known from tin-based CZTS kesterites¹⁶ and unfortunately suffer from instable solutions and inhomogeneous film formation. The water based ATG approach facilitates stable “green” solutions and good film formation, but is limited in terms of efficiency due to huge carbon residues as mentioned above.

In contrast, the DMF approach fulfills all of the above-mentioned requirements. It allows the smallest amount of carbon, since no acetates or ATG were used and therefore thiourea is the only carbon-containing substance. Although less environmentally friendly than water-based solutions, solution D is stable for several weeks and homogeneous samples can be prepared making it the most promising approach of the four solutions discussed.

Conclusions

Cu₂ZnGeS_xSe_{4-x} absorber layers have been prepared from four different metal salt solutions by a simple non-vacuum process. All approaches resulted in kesterite-type structures, but their morphology and sulfur-content showed clear differences. With the approach based on metal chlorides in DMF an efficiency of 5.1% could be achieved, which is the best reported value for this material.
