

## Catalytic synergy effect of MoS<sub>2</sub>/reduced graphene oxide hybrids for a highly efficient hydrogen evolution reaction†

Jung Eun Lee,<sup>‡,a</sup> Jaemin Jung,<sup>‡,a</sup> Taeg Yeoung Ko,<sup>a</sup> Sujin Kim,<sup>b</sup> Seong-Il Kim,<sup>c</sup> Junghyo Nah,<sup>d</sup> Sunmin Ryu,<sup>e</sup> Ki Tae Nam<sup>f</sup> and Min Hyung Lee<sup>\*a</sup>

Two-dimensional layered transition metal dichalcogenide (TMD) materials such as MoS<sub>2</sub> and WS<sub>2</sub> have received a great deal of attention as alternatives to Pt in hydrogen evolution reaction (HER) catalysts. Recently, confined synthesis of TMD nanoparticles on graphene exhibited great catalytic performance for HER, due to the presence of many active edge sites. However, the correlation of gradual electronic transition states of TMD/graphene hybrids to catalytic behavior has been rarely studied. By means of controlling only the graphene oxide (GO) content added during the solvothermal synthesis with MoS<sub>2</sub>, we have synthesized hybrids of MoS<sub>2</sub> and reduced graphene oxide (rGO) with tunable morphology; this tuning also brought about a gradual change in the electronic states of MoS<sub>2</sub> due to strain induced by van der Waals interaction between heterolayers. The GO content tuning gradually enhanced the HER catalytic performance of the MoS<sub>2</sub>/rGO hybrids, decreasing the Tafel slope from 82 to 48 mV per decade owing to synergistic effects of an increase of catalytically active areas, an electronic transition of MoS<sub>2</sub>, and conductivity of rGO substrates.

### 1. Introduction

Hydrogen production using photoelectrochemical water splitting has received a great deal of attention as a sustainable and clean way to convert solar energy to hydrogen energy. The material requirements of photoelectrochemical cells (*i.e.*, high visible absorption, slow recombination, and fast carrier transport, *etc.*) have some analogues to those of solar cells, but photoelectrochemical water splitting is more challenging due to further redox reaction steps using photogenerated carriers. Accordingly, kinetically effective transfer of carriers from semiconductors to electrolyte is a critical step to achieve high

solar-to-hydrogen efficiency. To improve the reaction kinetics, the development of HER cocatalysts with low overpotential is a very important issue. Pt has been considered to be the most effective catalyst for the HER, but its large-scale application is limited due to its scarcity and high cost. Therefore, much effort has been devoted to developing cocatalysts made of earth-abundant materials with HER catalytic performance comparable to that of Pt. Moly-based catalysts such as MoP sheets<sup>1,2</sup> and Mo<sub>2</sub>C nanoparticles<sup>3</sup> have been demonstrated to be HER catalysts with good stability and performance. Mono transition metal dichalcogenides (TMD) sheets such as MoS<sub>2</sub>,<sup>4–8</sup> MoSe<sub>2</sub>,<sup>7,9</sup> and WS<sub>2</sub><sup>10,11</sup> have been considered to be promising candidates to replace Pt. For MoS<sub>2</sub>, the most studied TMD catalyst, most research has focused on increasing the number of unsaturated sulfide edges, based on the understanding that these are the primary catalytically active sites.<sup>12</sup> In contrast to this point of view, Voiry *et al.* reported that the conductivity of the basal plane is a critical factor in the catalytic performance of MoS<sub>2</sub>.<sup>13</sup> Based on this idea, graphene has been used as MoS<sub>2</sub> support to enhance charge transfer.<sup>14,15</sup> Recently, several groups have demonstrated that the conversion of electronic structures of TMD from 2H to 1T drastically improve their HER catalytic performance.<sup>13,16</sup> To understand the mechanism of the HER catalytic behavior of TMD, investigation of the correlation between catalytic performance and electronic structural changes will be very important. Very recently, Wang *et al.* demonstrated continuous tuning of the electronic structure of chemical vapour deposition (CVD)-grown vertically aligned

$\text{MoS}_2$  by using electrochemical lithiation approaches.<sup>16</sup> However, synthetic approaches to gradually control the electronic states of  $\text{MoS}_2$  by using reduced graphene oxide (rGO) supports without lithium intercalation have been rarely studied, and the effect on catalytic performance of such tunability in  $\text{MoS}_2$ /rGO hybrids has been rarely reported so far.

In the present work, we developed facile routes to control the morphologies of  $\text{MoS}_2$ /rGO hybrids, including continuous control over the electronic state of  $\text{MoS}_2$  laid directly flat on rGO, by changing the ratio of  $\text{MoS}_2$  and rGO during a solvothermal synthesis.  $\text{MoS}_2$ /rGO hybrids synthesized by including an appropriate amount of rGO possessed many active sites because  $\text{MoS}_2$  was well dispersed on the rGO sheets; these materials achieved good conductivity of carriers, leading to low overpotential.

## 2. Experimental section

### 2.1 Synthesis of $\text{MoS}_2$ /rGO composites

Graphene oxide (GO) was synthesized from natural graphite flakes (Alfa Aesar, –325 mesh, 99.8% metal basis flakes) by using a modified Hummers method.<sup>17</sup> Graphite flakes of 1 g and 0.5 g of sodium nitrate ( $\text{NaNO}_3$ ) were put into a 250 ml round-bottom flask and then kept in an ice bath while slowly adding 23 ml of sulfuric acid ( $\text{H}_2\text{SO}_4$ ) with stirring. While maintaining mild agitation and keeping the reaction temperature below 20 °C, 3 g of potassium permanganate ( $\text{KMnO}_4$ ) was slowly added to the suspension. The ice bath was then removed and the suspension was heated in an oil bath to 35 °C; the suspension was maintained at this temperature for 1 h. As the reaction proceeded, the suspension gradually thickened and became paste-like. Then, 40 ml of DI water was added slowly with vigorous agitation while maintaining the oil bath condition. This reaction caused violent effervescence and increased the temperature of the suspension. When the temperature decreased to 40 °C, the suspension was diluted to 100 ml by addition of DI water and was then treated with 34.5% hydrogen peroxide until the suspension turned bright yellow. Next, the yellow suspension was vacuum-filtered, yielding a brown filter cake. The filter cake was washed with DI water and centrifuged at 4000 rpm for 10 min, and then was washed with 10% hydrochloric acid and centrifuged again at 4000 rpm for 10 min. Then, the material was rinsed four times by ultracentrifugation (30 000 rpm for 10 min) followed by resuspension in DI water. Then, the suspension was dialyzed by using a dialysis membrane (Spectra/Por) for 1 week, during which time the suspension reached approximately pH 7. Finally, the suspension was transferred to a plastic dish and dried in a convection oven at 60 °C for 12 h, yielding a free-standing GO film.

To synthesize  $\text{MoS}_2$ /rGO hybrids, 22 mg of  $(\text{NH}_4)_2\text{MoS}_4$  was added to various solutions of GO in DMF (2.5, 3.3, 5, and 10 mg of GO in 10 ml of DMF) and stirred at room temperature until the solutions were homogenous. Next, each solution was well dispersed by using an ultrasonic bath for 20 min, and was then transferred to a 40 ml Teflon-lined autoclave and kept in a convection oven at 200 °C for 10 h. The product was then centrifuged at 8000 rpm and washed with DI water. Next, the

solution was rinsed 5 times to completely remove DMF and organic residues. The final product was redispersed in 5 ml DI water. Pristine  $\text{MoS}_2$  was prepared by using the same procedure but without the addition of GO.

### 2.2 Electrochemical measurements

Homogeneous catalyst solutions of  $\text{MoS}_2$ /rGO hybrids and of pristine  $\text{MoS}_2$  were prepared by mixing 4 mg of catalyst with 80  $\mu\text{l}$  of 5 wt% Nafion solution, and then adding 0.2 ml of EtOH and 0.8 ml  $\text{H}_2\text{O}$  and ultrasonication the resulting mixture for 20 min. Then, 10  $\mu\text{l}$  portions of catalyst solution were deposited on glassy carbon working electrodes 3 mm in diameter and Pt working electrodes 2 mm in diameter with a PTFE body. All electrodes were dried at room temperature. Polarization curves were measured by using a three-electrode setup (using Pt mesh as a counter electrode, saturated calomel electrode (SCE) as a reference electrode, and the catalyst as a working electrode) in  $\text{N}_2$ -bubbled 0.5 M  $\text{H}_2\text{SO}_4$  using a scan rate of 10  $\text{mV s}^{-1}$ . The potential in 0.5 M  $\text{H}_2\text{SO}_4$  was converted from SCE to RHE by using the equation  $E(\text{RHE}) = E(\text{SCE}) + 0.273$  V. All electrochemical data reported herein are given in terms of potential *versus* RHE. *iR*-drop by solution resistance and parasitic resistance is corrected by the following equation:  $E_{iR\text{-corrected}} = E_{\text{RHE}} - iR_{\Omega}$ , where  $iR_{\Omega}$  is *iR*-drop and  $E_{\text{RHE}}$  is the potential *vs.* reversible hydrogen electrode. The Tafel slopes of all  $\text{MoS}_2$ /rGO samples are calculated by compensating the *iR*-drop. EIS measurements were performed using the same experimental setup, at the overpotential  $\eta = 180$  mV (bias: –0.45 V *vs.* SCE from 100 000 to 0.01 Hz with amplitude 0.01 V).

### 2.3 Material characterization

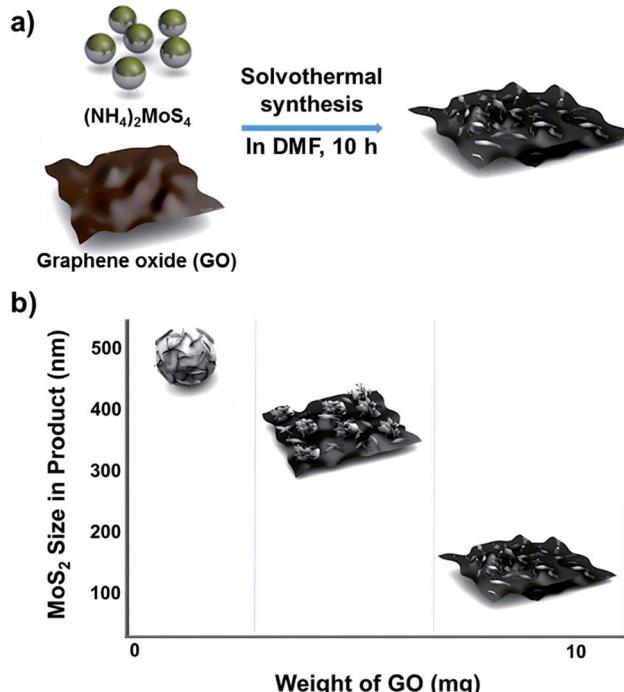

The synthesized materials were characterized by means of XPS (Thermo Electron K-Alpha), XRD (D8 Advance equipped with a Cu K $\alpha$  source), high-resolution TEM (HRTEM; JEOL JEM-2100 F, 200 kV), field emission scanning electron microscopy (FESEM; LEO SUPRA 55). Raman spectra were measured by using a custom-built micro-Raman setup detailed elsewhere;<sup>18</sup> briefly, an Ar ion laser operated at 514 nm with 1 mW output was focused to a diffraction-limited spot on the samples by using an objective lens (40 $\times$ , numerical aperture 0.60). The Raman signal collected by the same lens was fed to a liquid nitrogen-cooled charge-coupled device detector (Princeton Instruments, SPEC-10) coupled with a spectrograph with a focal length of 30 cm (Princeton Instruments, SP-2300). The spectral resolution was determined to be 3  $\text{cm}^{-1}$  and the spectral accuracy was better than 1  $\text{cm}^{-1}$ .<sup>18</sup>

## 3. Results and discussion

### 3.1 Synthesis and characterization of $\text{MoS}_2$ /rGO hybrids

The method used to control the morphology of  $\text{MoS}_2$  is summarized in Scheme 1. First, GO was synthesized by using a modified Hummer's method (see Experimental section).<sup>17</sup> The GO solution thus prepared was rinsed with deionized (DI) water and dried to make GO sheets. The desired amount of GO sheets was weighed, and then dispersed into a solution of  $\text{MoS}_2$

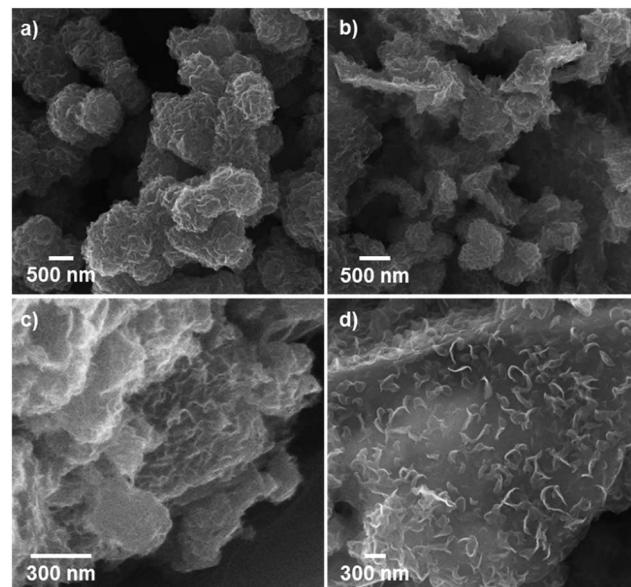

**Scheme 1** Schematic description of (a) the synthetic approach for MoS<sub>2</sub>/rGO hybrids and (b) morphology and size changes depending on the GO content in the precursor solution.

precursors in dimethylformamide (DMF). Next, the solution of GO and MoS<sub>2</sub> precursors was placed into a Teflon-lined autoclave and kept in a convection oven at 200 °C for 10 h. During this solvothermal process, MoS<sub>2</sub> grew on the GO layers, and GO was simultaneously changed to reduced graphene oxide (rGO). Although MoS<sub>2</sub> was grown on single layer rGO sheets, the final products look like intercalation of MoS<sub>2</sub> between the rGO layers due to stacking of the rGO layers.

Pure MoS<sub>2</sub> samples and MoS<sub>2</sub>/rGO hybrids synthesized by means of the solvothermal process had different morphologies depending on the amount of GO included during the synthesis (Fig. 1). When MoS<sub>2</sub> was synthesized without added GO, submicron-scale spherical particles consisting of highly packed corrugated MoS<sub>2</sub> layers resulted (Fig. 1a). Pure MoS<sub>2</sub> layers tend to stack onto each other by means of van der Waals interactions,<sup>12</sup> and tend to minimize surface energy by agglomerating to form spherical shapes. Accordingly, fewer catalytically active edge sites were available in this material compared to isolated nanoparticulate MoS<sub>2</sub>.

When the solvothermal process was performed including MoS<sub>2</sub> precursor solution (fixed at 22 mg) and various amounts of GO, MoS<sub>2</sub>/rGO hybrids were synthesized (Fig. 1b-d). The interactions between MoS<sub>2</sub> precursor and rGO were clearly reflected in the changes in MoS<sub>2</sub>/rGO morphology observed as the amount of GO was increased. First, the amount of GO affected the amount of MoS<sub>2</sub> sheets loaded on the GO, because GO oxygen functional groups such as carbonyls and other defect sites play an important role in nucleating MoS<sub>2</sub> growth.<sup>15,19,20</sup> Second, the stacked GO sheets interfere with the growth of MoS<sub>2</sub> in the (002) direction through the layer confinement effect;<sup>15,19</sup>

**Fig. 1** SEM images showing the different morphologies of (a) pristine MoS<sub>2</sub> and (b-d) MoS<sub>2</sub>/rGO hybrids prepared using various GO contents: (b) MS-GO<sub>1</sub>, (c) MS-GO<sub>3</sub>, and (d) MS-GO<sub>4</sub>.

thus, increasing the GO content decreases the number of stacked MoS<sub>2</sub> layers. When the GO content was used as 2.5 mg (a composition denoted as MS-GO<sub>1</sub>), thick-layered MoS<sub>2</sub>/rGO composites were synthesized (Fig. 1b). Also, spherical MoS<sub>2</sub> particles were observed that had smaller diameters (200–500 nm) than those formed in the pure MoS<sub>2</sub> sample (Fig. 1a). That is to say, the low GO content in MS-GO<sub>1</sub> provided relatively few nucleation sites, still allowing aggregation of MoS<sub>2</sub> layers to occur, albeit to a lesser extent than in the reaction yielding pure MoS<sub>2</sub>. When the GO content was increased to 5 mg (denoted as MS-GO<sub>2</sub>), small spherical MoS<sub>2</sub> particles were observed that lay flat on rGO layers, and much less MoS<sub>2</sub> aggregation was observed compared to that in MS-GO<sub>1</sub> (Fig. S1a†). However, both MS-GO<sub>1</sub> and MS-GO<sub>2</sub> had nanoparticulate rather than sheet morphology, and thus did not achieve the desired homogeneous distribution of MoS<sub>2</sub> on rGO sheets. When the GO content was increased to 5 mg (denoted as MS-GO<sub>3</sub>), most rGO was well decorated with layered MoS<sub>2</sub> and no spherical MoS<sub>2</sub> particle was observed, indicating that the GO provided a sufficient number of nucleation sites to avoid aggregation (Fig. 1c). When the GO content of 10 mg was used (denoted as MS-GO<sub>4</sub>), well distributed MoS<sub>2</sub> sheets were observed with lower loading density on the rGO compared to that observed for MS-GO<sub>3</sub> (Fig. 1d). Importantly, the amount of GO needs to be balanced: the GO content should provide sufficient nucleation sites to avoid aggregation of MoS<sub>2</sub>, but should be low enough to maintain a high density of MoS<sub>2</sub> in the resulting material. When the GO content was increased further while maintaining the MoS<sub>2</sub> precursor content and the total synthetic volume, the greater GO content provided more nucleation sites, but lowered the density of MoS<sub>2</sub> due to the excess of nucleation sites relative to the MoS<sub>2</sub> content. This effect was clearly observed when the solvothermal synthesis was performed with excess amounts of

GO (over 10 mg); for example, when the GO content was 20 mg, the loading density of  $\text{MoS}_2$  on the rGO sheets was drastically decreased (Fig. S1b†). This result indicates that the morphological changes of  $\text{MoS}_2$ /rGO depend on the ratio of GO and  $\text{MoS}_2$  precursor amounts.<sup>14,21</sup> In our study, the  $\text{MoS}_2$ /rGO ratio is controlled by changing the amount of GO only, with a fixed amount of  $\text{MoS}_2$  precursor. Decreased aggregation and size of  $\text{MoS}_2$  can be achieved by increasing GO, but this is a trade-off with the low loading density of  $\text{MoS}_2$ . Therefore, it is important to choose an appropriate amount of GO (10 mg of GO in our case) to obtain the optimum HER catalytic performance with a homogeneous distribution and appropriate loading density for  $\text{MoS}_2$ . The reproducibility of the proposed morphology control and catalytic performance of each hybrid are confirmed in tens of experiments.

To verify the quality of  $\text{MoS}_2$  hybridized on rGO, transmission electron microscope (TEM) images of  $\text{MoS}_2$ /rGO hybrids were acquired. TEM images of aggregated spheres of pristine  $\text{MoS}_2$  revealed the stacking of layers within these particles (tens of layers with approx. 0.67 nm interlayer distance; Fig. 2a–c). In a low-magnification TEM image of  $\text{MoS}_2$ /rGO hybrids (MS-GO<sub>4</sub>),  $\text{MoS}_2$  was observed throughout the surface of crumpled rGO layers (Fig. 2d), which were formed by self-assembly of the

flexible graphene layers during the solvothermal synthesis.<sup>21,22</sup>  $\text{MoS}_2$  basal planes were clearly observed to sit parallel on the rGO (Fig. 2d–f). Unlike the structure of pristine  $\text{MoS}_2$ ,  $\text{MoS}_2$  sheets grown on rGO had fewer (around three to five) stacked  $\text{MoS}_2$  layers, with an interlayer distance of about 0.67 nm, as observed from a folded edge in the hybrid material (Fig. 2f). Energy-dispersive X-ray spectroscopy (EDS) mapping of selected areas of pure rGO and a  $\text{MoS}_2$ /rGO hybrid confirmed that  $\text{MoS}_2$  was well hybridized on rGO (Fig. S2†) and verified that Mo and S were distributed uniformly over the rGO sheets. SAED patterns indicated that the  $\text{MoS}_2$  in the hybrids was polycrystalline (Fig. S3†); the  $\text{MoS}_2$  was indexed as a hexagonal phase randomly oriented on the rGO.<sup>19,23</sup> Broad peaks in the X-ray diffraction (XRD) spectra of the hybrids confirmed the amorphous nature of  $\text{MoS}_2$  in the hybrids (Fig. S4†). The poor crystallinity of  $\text{MoS}_2$  was due to the incorporation of graphene, which interfered with the growth of  $\text{MoS}_2$  crystals.<sup>21</sup>

Raman spectroscopy was used to further investigate the structure changes of  $\text{MoS}_2$ /rGO. Raman spectra of all  $\text{MoS}_2$ /rGO samples showed three distinct peaks corresponding to the graphene bands of D (1351  $\text{cm}^{-1}$ ), G (1587  $\text{cm}^{-1}$ ), and 2D (2691  $\text{cm}^{-1}$ ; Fig. 3a). It is worth notice that the G band of GO

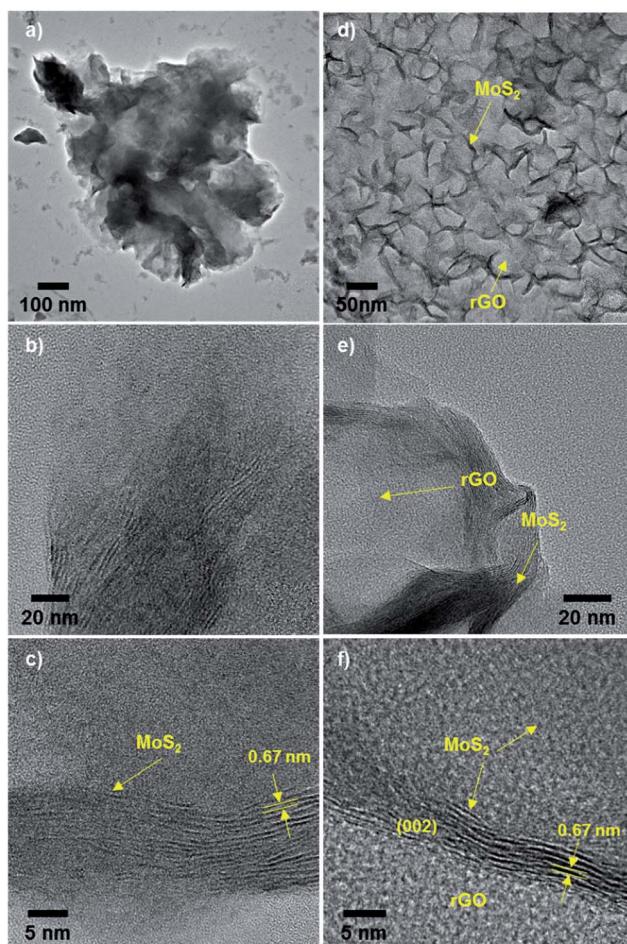

Fig. 2 TEM and HRTEM images of (a–c) pristine  $\text{MoS}_2$  and (d–f)  $\text{MoS}_2$ /rGO hybrids.

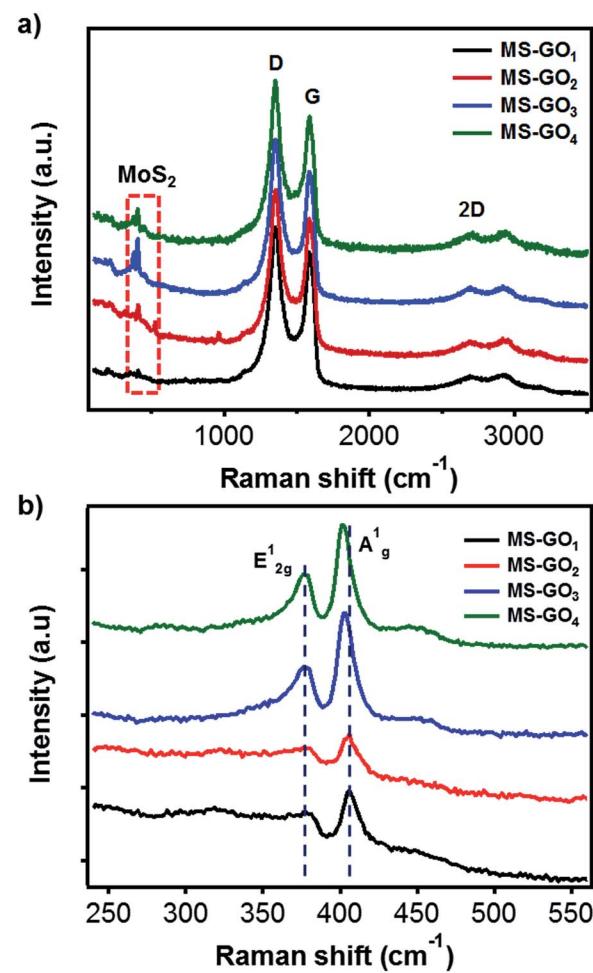

Fig. 3 Raman spectra of  $\text{MoS}_2$ /rGO hybrids prepared using various GO contents: (a) rGO and (b)  $\text{MoS}_2$  peak regions.

(1603 cm<sup>-1</sup>) was downshifted for bare rGO (1595 cm<sup>-1</sup>) due to the recovery of sp<sup>2</sup> conjugation. The MoS<sub>2</sub>/rGO hybrids exhibited further downshift of G bands (1588 cm<sup>-1</sup>), which can be attributed to further reduction or addition of N atom possibly come from DMF or ammonium tetrathiomolybdate.<sup>24,25</sup> The downshift of G modes also might be caused by strain on rGO faced with MoS<sub>2</sub> by lattice mismatching (Fig. S5†).<sup>26</sup> Basically, the D band corresponds to the A<sub>1</sub>' vibration mode. In the case of perfect graphene, this mode cannot be observed by Raman scattering due to the perfect lattice symmetry. Thus, the D band responded to the vibrations of carbon atoms with in-plane terminations of disordered graphite dangling bonds. The G band, which is commonly found in graphite materials, responded to vibrations of carbon atoms in the opposite direction from each other with the adjacent atoms, and is due to the symmetry of E<sub>2g</sub>. Measuring the ratio of D and G bands intensity ( $I_D/I_G$ ) is a useful indicator for estimating the quality of the graphite crystal structures. Crucially, in the case of rGO hybrid composites,  $I_D/I_G$  value can provide information on the unrepaired defects of rGO quantitatively. These defect sites on the rGO could play a critical role for the nucleation point during the synthesis of hybrid materials; therefore, we can estimate the amount of nucleation sites for MoS<sub>2</sub> from the  $I_D/I_G$  value.<sup>27</sup> In our study  $I_D/I_G$  was 1.140, 1.141, 1.191, and 1.220 for MS-GO<sub>1</sub>, MS-GO<sub>2</sub>, MS-GO<sub>3</sub>, and MS-GO<sub>4</sub>, respectively; this trend indicates that an increase in total defect sites (*i.e.*, increase of nucleation sites for MoS<sub>2</sub>) results from increasing the GO amount. This shows why increasing the GO amounts inhibits the agglomerate of MoS<sub>2</sub> gradually. Characteristic Raman peaks of MoS<sub>2</sub> corresponding to the E<sub>2g</sub><sup>1</sup> in-plane vibrational mode at 376 cm<sup>-1</sup> and the A<sub>g</sub><sup>1</sup> out-of-plane vibrational modes at 403 cm<sup>-1</sup> were observed for all MoS<sub>2</sub>/rGO hybrids (Fig. 3b). The A<sub>g</sub><sup>1</sup> peaks of MS-GO<sub>3</sub> and MS-GO<sub>4</sub> were of lower frequency than those of MS-GO<sub>1</sub> and MS-GO<sub>2</sub>, indicating that MS-GO<sub>3</sub> and MS-GO<sub>4</sub> had fewer MoS<sub>2</sub> layers because increased GO-MoS<sub>2</sub> interactions interfere the stacking of MoS<sub>2</sub> attributed to van der Waals interaction between hetero interface of MoS<sub>2</sub> and rGO.<sup>28,29</sup>

X-ray photoelectron spectroscopy (XPS) data gave clues regarding the electronic states of MoS<sub>2</sub>/rGO hybrids (Fig. 4). C 1s peak analysis of MoS<sub>2</sub>/rGO hybrids showed a decrease in the intensity of the C–O peak (286 eV) relative to that of the GO precursor, indicating the successful reduction of GO during the solvothermal process (Fig. S6†).<sup>30,31</sup> Five distinct peaks were observed in Mo 3d spectra of pristine MoS<sub>2</sub> and of all MoS<sub>2</sub>/rGO hybrids (Fig. 4a): pristine MoS<sub>2</sub> showed peaks of 3d<sub>5/2</sub> (228.98 eV) and Mo 3d<sub>3/2</sub> (232.08 eV), and these peaks gradually shifted to lower binding energy as the GO content was increased up to 10 mg (3d<sub>5/2</sub> at 228.28 eV and 3d<sub>3/2</sub> at 231.48); the binding energy was very close to reported value of 1T-MoS<sub>2</sub>. The peak shifts indicated that the electron transfer might take place in between MoS<sub>2</sub> sheets and rGO, and this transfer is more favourable for hybrids with high rGO contents. The transfer gives positive effect for catalytic performance with improved electronic and ionic conductance.<sup>25</sup> We carefully predict the electronic state changes by degree of van der Waals interaction depending on amount of rGO based on Raman and the XPS change. In addition to the Raman studies, the XPS peak shifts

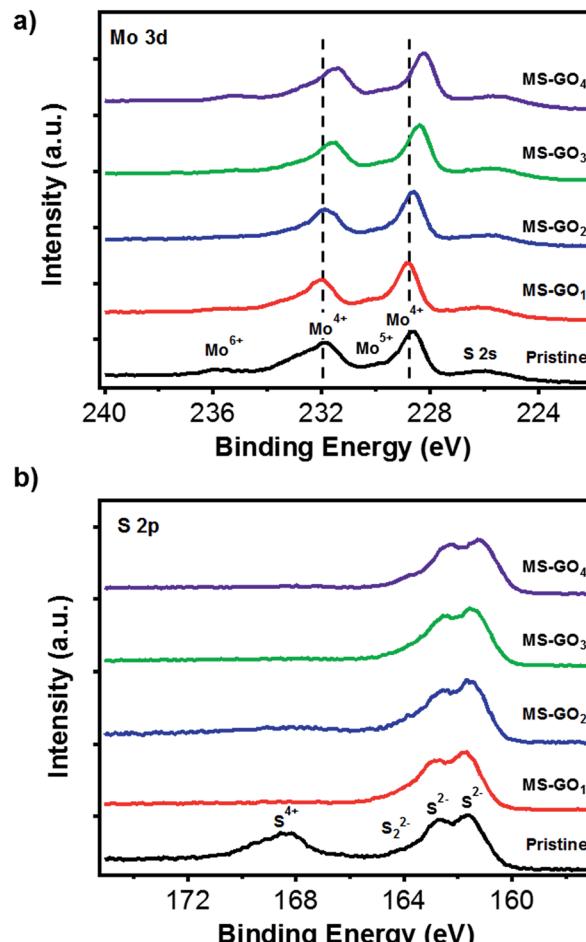

Fig. 4 (a) Mo 3d and (b) S 2p XPS spectra of pristine MoS<sub>2</sub> and of MoS<sub>2</sub>/rGO hybrids with various GO contents.

indicated that the GO content used during MoS<sub>2</sub>/rGO synthesis not only changed the morphology of the MoS<sub>2</sub>, but also induced a gradual change in the MoS<sub>2</sub> electronic state due to van der Waals interaction between hetero 2D layers.<sup>13,29,32</sup> The peak observed at 236.0 eV was a residual peak from the +6 oxidation state, arising from slight oxidation during the experiment.<sup>33</sup> The small shoulder at 230 eV was evidence of a trace of conversion from Mo<sup>6+</sup> to Mo<sup>5+</sup>.<sup>34–36</sup> High-resolution XPS images of the S 2p doublet around 161 eV (S 2p<sub>3/2</sub>) and 162 eV (S 2p<sub>1/2</sub>) showed that the S 2p binding energies of MS-GO<sub>1</sub> and MS-GO<sub>2</sub> were similar to those of pristine MoS<sub>2</sub> (161.58 and 162.68 eV), but these peaks were downshifted (161.28 and 162.18 eV) in MS-GO<sub>3</sub> and MS-GO<sub>4</sub>. The shoulder around 164 eV indicated that bridged S<sub>2</sub><sup>2-</sup> or apical S<sub>2</sub><sup>2-</sup> were present; these are considered to be active HER species (Fig. 4b).<sup>15,34–36</sup>

### 3.2 Electrochemical properties of MoS<sub>2</sub>/rGO hybrids

To test the electrocatalytic HER performance of MoS<sub>2</sub>/rGO hybrids, electrochemical analyses were carried out using MoS<sub>2</sub>/rGO coated on glassy carbon working electrodes. The polarization curves of pristine MoS<sub>2</sub> exhibited the onset potential—defined here as the potential at  $j = -3 \text{ mA cm}^{-2}$ —of  $-0.347 \text{ V}$

(Fig. 5a). Compared to the pristine  $\text{MoS}_2$ ,  $\text{MS-GO}_1$  had a large positive shift of the onset potential, to  $-0.207$  V. The polarization curves of  $\text{MS-GO}_2$ ,  $\text{MS-GO}_3$ , and  $\text{MS-GO}_4$  hybrids showed the onset potentials of  $-0.157$ ,  $-0.147$ , and  $-0.152$  V, respectively; the onset potential of  $\text{MS-GO}_3$  was shifted positively by about 200 mV compared to that of pristine  $\text{MoS}_2$ . The measured current densities of  $\text{MoS}_2/\text{rGO}$  hybrid electrodes at  $-200$  mV were  $-24.6$ ,  $-24.4$ ,  $-16.1$ , and  $-3.0$   $\text{mA cm}^{-2}$  for  $\text{MS-GO}_4$ ,  $\text{MS-GO}_3$ ,  $\text{MS-GO}_2$ , and  $\text{MS-GO}_1$  hybrids, respectively. Compared to  $\text{MoS}_2/\text{rGO}$  hybrids, pure  $\text{MoS}_2$  exhibited the much lower current density of  $-0.8$   $\text{mA cm}^{-2}$ .

Tafel plots were prepared using the polarization curve data after correction of the potential by the ohmic potential drop ( $iR$ ) losses induced by the resistance between the electrolytes and the electrode. Tafel slopes were calculated by using the Tafel equation (Fig. 5b).<sup>37</sup> Pristine  $\text{MoS}_2$  showed the highest Tafel slope ( $178$  mV dec.<sup>-1</sup>) among the samples studied;  $\text{MS-GO}_1$  had a much lower Tafel slope ( $82$  mV dec.<sup>-1</sup>), and  $\text{MS-GO}_2$  had the Tafel slope of  $60$  mV per decade. The Tafel slope of  $\text{MS-GO}_4$  was the lowest ( $48$  mV dec.<sup>-1</sup>) among all the  $\text{MoS}_2/\text{rGO}$  hybrids studied.  $\text{MS-GO}_3$  had a similar Tafel slope ( $50$  mV dec.<sup>-1</sup>) to that of  $\text{MS-GO}_4$ , which was expected because of these materials' similar morphologies and electronic states. Pt, a well-known HER catalyst, was compared to estimate catalytic performance of  $\text{MoS}_2/\text{rGO}$  hybrids, and it shows  $18$  mV per decade lower Tafel slope ( $30$  mV dec.<sup>-1</sup>) than  $\text{MS-GO}_4$ . The Tafel slopes of the  $\text{MoS}_2/\text{rGO}$  hybrids could be used to estimate the kinetics of the HER on these materials based on the Heyrovsky reaction, which

is the rate-determining step in the electrochemical desorption.<sup>14,38</sup> Contrastingly,  $\text{MoS}_2/\text{rGO}$  hybrids with excess GO content had worse onset potential and higher Tafel slope than those with lower GO content. For example, the onset potential of  $\text{MoS}_2/\text{rGO}$  synthesized with  $20$  mg of GO was more negative than that synthesized with  $10$  mg of GO ( $\text{MS-GO}_4$ ), and the corresponding Tafel slope ( $53$  mV dec.<sup>-1</sup>) was higher than that of both  $\text{MS-GO}_3$  and  $\text{MS-GO}_4$  (Fig. S7a and b†). These data show that the use of excessive GO decreases the  $\text{MoS}_2$  loading density (and thus the density of catalytically active sites) in the resulting hybrid (Fig. S1b†). This effect deteriorates the overall catalytic performance. That is to say, the GO content used can not only control the  $\text{MoS}_2/\text{rGO}$  hybrids' morphology, but can also affect their catalytic performance in terms of conductivity and the number of active edge sites. All electrochemical characterizations are summarized in ESI Table S1.†

Electrochemical impedance spectroscopy (EIS) was conducted to compare the hybrids' electrical transport and electrode kinetics characteristics. Nyquist plots were prepared for each hybrid based on a Randles equivalent circuit model (Fig. 5c); all  $\text{MoS}_2/\text{rGO}$  hybrids showed series resistances ( $R_s$ ) of about  $10\ \Omega$ , suggesting good conductivity of the electrolytes. Importantly, charge transfer resistance ( $R_{CT}$ ) at the interfaces between the glassy carbon and the  $\text{MS-GO}$  hybrids and between  $\text{MS-GO}$  and electrolytes increased in the following order:  $\text{MS-GO}_3$  ( $25.59\ \Omega$ )  $<$   $\text{MS-GO}_4$  ( $31.56\ \Omega$ )  $<$   $\text{MS-GO}_2$  ( $104.6\ \Omega$ )  $<$   $\text{MS-GO}_1$  ( $242.0\ \Omega$ ). This observed trend supports the explanation that charge transfer is enhanced because of a transition of  $\text{MoS}_2$

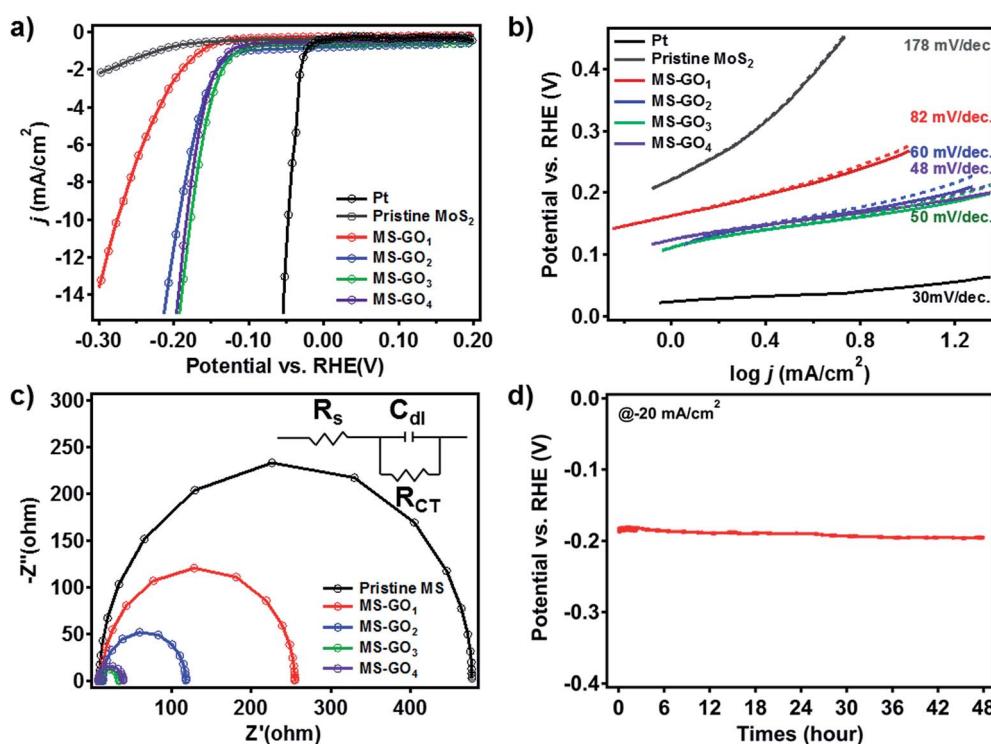

Fig. 5 Electrochemical characterizations of pristine  $\text{MoS}_2$  and  $\text{MoS}_2/\text{rGO}$  hybrids. (a) Polarization curves of  $\text{MoS}_2$  and  $\text{MoS}_2/\text{rGO}$  hybrids. (b) Tafel plots obtained from the polarization curve data in (a), (dashed lines) before and (solid lines) after  $iR$  correction. (c) Nyquist plots of pristine  $\text{MoS}_2$  and of  $\text{MoS}_2/\text{rGO}$  hybrids. (d) Long-term stability test for the  $\text{MS-GO}_4$  HER catalyst.

crystals to a more conductive electronic phase (Fig. 5c). Also, the higher amount of rGO in good contact with  $\text{MoS}_2$  of high density can improve the conductivity of a  $\text{MoS}_2$ /rGO hybrid, thereby enhancing the charge transfer. The low  $R_{\text{CT}}$  observed for  $\text{MS-GO}_3$  and  $\text{MS-GO}_4$  is strong evidence of these hybrids' fast electrode kinetics (*i.e.*, good catalytic performance). Furthermore, the double-layer capacitance ( $C_{\text{DL}}$ ) of the MS-GO hybrids was extracted based on the equivalent circuit model to provide information on the active surface area.  $\text{MS-GO}_3$  and  $\text{MS-GO}_4$  showed the highest  $C_{\text{DL}}$  (3.9 and 4.2 mF) among the samples studied (Table S2†), indicating that these hybrids have a large active surface area of the electrode.<sup>39</sup> The high  $C_{\text{DL}}$  values of  $\text{MS-GO}_3$  and  $\text{MS-GO}_4$  originated from the density of the  $\text{MoS}_2$  sheet's distribution on the rGO, which depended on the relative contents of  $\text{MoS}_2$  and rGO. Therefore, to achieve both good charge transfer and high active surface area, precise control is required over the ratio of  $\text{MoS}_2$  to rGO content used during the synthesis of the hybrids.

To evaluate the stability of the  $\text{MoS}_2$ /rGO hybrid as a HER catalyst, we performed durability test over 48 h by chronopotentiometry (Fig. 5d). Overpotential drift at the static current of  $-20 \text{ mA cm}^{-2}$  was less than 10 mV after the test, showing good long-term stability of the catalyst toward HER. Besides, we carried out 1000 consecutive cycles of cyclic voltammetry for  $\text{MS-GO}_4$  under potential between 0 and  $-0.3 \text{ V}$  *versus* a reversible hydrogen electrode (RHE); negligible current density change was observed during the test, suggesting superior long-term stability as a HER catalyst (Fig. S8†).

## 4. Conclusion

In conclusion, we have demonstrated the morphology-dependent HER catalytic performance of  $\text{MoS}_2$ /rGO hybrids. The morphology of  $\text{MoS}_2$ /rGO hybrids was well controlled by simply changing the content of rGO used during solvothermal synthesis, relative to the  $\text{MoS}_2$  content. When an appropriate amount of GO was used, the resulting  $\text{MoS}_2$ /rGO hybrids had a high density of homogeneously distributed  $\text{MoS}_2$  sheets on the rGO, yielding many catalytically active edge sites; also, using the appropriate GO content yielded good contact between the  $\text{MoS}_2$  and rGO and caused the electronic states of  $\text{MoS}_2$  to transition to a more conductive phase, increasing the hybrids' conductivity. The synthetic approach discussed herein can be applied to other TMD/rGO hybrids as well as other layered materials.
