L-Cysteine electrooxidation in alkaline and acidic media: a combined spectroelectrochemical and computational study†

André H. B. Dourado,^a Ana P. de Lima Batista,^b Antonio G. S. Oliveira-Filho,^b Paulo T. A. Sumodjo‡^a and Susana I. Cordoba de Torresi*^a

Due to the numerous possible oxidation states of sulfur, L-cysteine and L-cystine are very important amino acids that are utilized to understand the adsorption and redox activity of proteins and peptides. Therefore, the study of the adsorption/oxidation of these molecules can be used as a model system to understand protein behaviour. The aim of the present communication is to study this adsorption/oxidation process by infrared spectroscopy and DFT/PBE-D3/def2-SVP/COSMO (water) calculations. A bridge geometry (S bonded to two Pt atoms) was found to be the chemical adsorption link formed, and experimental data corroborate the DFT predictions. For both species, the surface–carboxyl group interaction is stronger at lower pH values, and the conformations of the adsorbed species were found to be dependent on the pH, with the amino group getting closer to the surface along with increases in the electrolyte alkalinity. The oxidation study was also performed at different pH values, and a Kolbe decarboxylation was found to be a side reaction at every pH, being more important in strong acidic solutions. Sulfur-containing adsorbed oxidized species were inferred based on the optimized structures of the adsorbed/desorbed species. A complex oxidation mechanism is proposed here, and species, such as sulfoxide, adsorbed sulfoxide, sulfenic and sulfinic acids and adsorbed sulfone, are suggested as intermediates in the oxidation of L-cysteine to sulfonic acid.

1. Introduction

L-Cysteine (L-Cys) and L-cystine (L-Cys₂) have attracted attention for a long time^{1–3} due to their importance as model molecules for enhancing the understanding of the redox activity of peptides and proteins.^{4,5} However, there are still several aspects concerning the electron transfer reactions of these molecules, with potential interest in biological systems,⁵ that need clarification and further investigation.

The reactions for the adsorption and oxidation of cysteine on solid electrodes, based on the known reactivity of alkanethiols, are displayed in Scheme 1. The proposed mechanism⁶ is supported by classical electrochemical techniques,^{1,2,5,7–11} such as cyclic voltammetry,^{1,2,5,7–9} step potential¹¹ and only a few spectroscopic experiments.³ It is not completely accepted because there is some controversy regarding the oxidation state of the

products and the number of electrons involved in each step of the oxidation reaction. For instance, Enache *et al.*⁵ and Feliciano-Ramos *et al.*¹⁰ suggest the presence of intermediates that are not adsorbed onto the electrode surface, such as sulfenic and sulfinic acids⁵ and desorbed sulfone;¹⁰ while other authors² note the occurrence of other adsorbed intermediates, such as sulfone species.

To elucidate the chemistry of L-Cys and L-Cys₂ on metallic electrodes, a combination of techniques that includes spectroscopic and computational approaches have been employed.^{12–20} Among these, we highlight the use of surface-enhanced Raman spectroscopy (SERS)^{12,13} and surface-enhanced second-harmonic

‡ In memoriam.

generation (SESHG)¹⁶ measurements to determine the orientation of L-Cys molecules adsorbed on a silver electrode and the use of density functional theory (DFT) calculations to investigate the adsorption of L-Cys onto both Au(111)^{19,20} and Ag(111).^{15–18}

In this work, we report an investigation of the interaction between L-cysteine, and its oxidation products, with a platinum electrode, in acidic and alkaline media. Spectroelectrochemical experiments in the infrared region (Infrared Reflection Absorption Spectroscopy – IRRAS) and DFT calculations were employed to explore the reaction intermediates of L-Cys and L-Cys₂ oxidation to contribute to the understanding and elucidation of the electrooxidation process of these molecules.

2. Experimental details

L-Cysteine and L-cystine (Sigma-Aldrich) were used without further purification. The following electrolytic solutions were used: H₂SO₄ 0.50 mol L⁻¹, Na₂SO₄ 0.50 mol L⁻¹ and NaOH 0.50 mol L⁻¹. L-Cys was used in 0.1 mol L⁻¹, while L-Cys₂ in saturated solution (0.5 × 10⁻³ mol L⁻¹). The pH of the neutral solution was adjusted by the addition of NaOH and/or H₂SO₄ for the intermediate values. Milli-Q water was used for preparing all solutions, all experiments were handled at room temperature, and N₂ was bubbled for an O₂ free solution.

A Thermo-Nicolet 6700 FTIR spectrometer (gain 4, 0.6329 optical velocity, 4 cm⁻¹ resolution, 98 accumulations, 59.49 s per measurement) coupled with an Autolab potentiostat/galvanostat (AUT85732) was used for the spectroelectrochemical experiments. A thin layer electrochemical cell with a ZnSe window was used, with pathlength around 0.072 cm (estimated by $b = n/(2\Delta\nu)$, with b as pathlength, n the number of fringes and $\Delta\nu$ the wavelength range). A Pt disk (5 mm radius) was used as the working electrode. A Pt grid and an Ag|AgCl (KCl_{sat}) were used as the auxiliary and the reference electrodes, respectively. The working electrode was polished using alumina (3 and 0.5 μm) and chemically cleaned by piranha solution (4 : 1 v/v H₂SO₂ : H₂O₂). The cell, Luggin capillary and counter electrode were also cleaned in piranha solution 20 hours before the measurements.

For electrochemical measurements, the electrode was placed in the thin layer cell, wait for the adsorption process to occur, while spectra were accumulated, and then polarized to more positive potential values. After each potential, the electrode was taken from the solution and cleaned in piranha solution again. While this procedure was performed, the cell was purged with N₂. After, the electrode was inserted in the cell again and the adsorption/polarization procedure was performed for a more positive potential. This protocol was used to assure the absence of atmospheric gases, as O₂ and CO₂, since the use of just one process for all potential values should take a long time, which could contaminate the solution.

3. Theoretical approach

3.1 Computational methods

All computational calculations were performed using the ORCA program package (version 3.0.3).²¹ The conductor-like screening

model (COSMO)²² was used to simulate water ($\epsilon = 80.4$) solvation effects. Energies, frequencies and geometric parameters were obtained with the PBE²³ density functional in conjunction with the resolution-of-the-identity (RI) approximation.²⁴ To take into account dispersion effects, Grimme's dispersion (D3) correction^{25,26} with the Becke–Johnson (BJ) damping parameter²⁷ was considered. The PBE density functional was chosen because it has been broadly used in studies involving Pt surfaces. In the explored potential energy surfaces (PES), all the structures were characterized as minima presenting only non-imaginary frequencies.

The Ahlrichs def2-SVP^{28,29} basis set was employed for all atoms, and an effective core potential (ECP) (SD(60, MWB))³⁰ and matching basis sets were used for the Pt atoms all throughout this work. The def2-SVP/J Coulomb fitting basis was applied for the resolution of identity.^{31,32} The present level of theory is referred to as DFT/PBE-D3/def2-SVP/COSMO (water) throughout this work.

3.2 Molecular cluster models

The purpose of these calculations is to identify potential structures for the L-Cys and L-Cys₂ molecules, and their oxidized forms, adsorbed on the Pt electrode surface. The first step towards this goal consists in the selection of a ideal Pt surface model. In broad terms, there are two ways to model surfaces and the interaction between surfaces and molecules: the slab and the cluster models.³³ In this study, we use the cluster model. It is worth to mention that cluster models might be subject to the following limitations: the coverage effect, as a single molecule interacts with the surface; the edge effects, as a small cluster may not represent the structure of the bulk, especially around the edges; and the charge effects, as in a cluster there is a small number of atoms, compared to the bulk, to delocalize the charge. For examples of the use of slab models, please see ref. 34–38.

The use of models that include a finite number of atoms allows the description of local electronic properties. A molecular cluster with 20 Pt atoms as displayed in Fig. 1 modelled the electrode surface. This cluster was used by Daramola and Botte³⁹ to investigate NH₃ adsorption on the Pt(111) surface and

Fig. 1 The Pt cluster and its interaction with L-Cys and L-Cys₂ systems. The sites on the surface and the interacting region of the molecule are highlighted in dark blue.

by Dhar and Cavallotti⁴⁰ in the study of the electrochemical reduction of carbon dioxide on Pt electrodes. To avoid edge effects, only the Pt atoms in the first layer were allowed to relax during the optimizations (Fig. 1a), while the Pt atoms in the second and third layers had their positions fixed. In the ground state, which is the electronic state considered in the current investigation, this cluster is neutral and its spin multiplicity is 15.³⁹ Considering the Wigner–Witmer rules for spin coupling, the allowed multiplicities for the electronic states of a supermolecule formed by the Pt₂₀ cluster (with spin multiplicity 15) and the cysteine radical, and its derivatives, (with spin multiplicity 2) are 14 and 16. As the chemisorption of cysteine and its derivatives on the Pt surface is effective with the pairing of electrons on a bonding orbital, the spin multiplicity of the electronic state investigated in our work is 14. As the reaction proceeds adiabatically on this electronic state, all bonded structures also correspond to electronic states with spin multiplicity 14.

The adsorption of L-Cys was investigated with the molecule in a radical form, without the hydrogen atom of the thiol group. The sulfur atom was placed near the Pt surface in four different positions. The different interaction sites, depicted in Fig. 1a, are labelled top (T), bridge (B), face-centred cubic (F) and hexagonal close-packed (H) positions. For each one of these sites, the L-Cys radical is parallel to the surface, *i.e.*, in a prone position, as displayed in Fig. 1b. This conformation provides extended contact between the Pt surface and the L-Cys functional groups, thus yielding a more stabilized structure when compared to a conformation that is perpendicular to the surface.

The study of the possible protonated, unprotonated, neutral, and oxidized forms of the L-Cys molecule on the Pt cluster were carried out only at the most energetically favoured adsorption site, the bridge position. Protonated and unprotonated forms of the L-Cys–Pt systems are potential structures in acidic and alkaline media, respectively. A neutral species, however, should

be present at a pH close to its neutral value. For the L-Cys₂ system, the S–S moiety, which is the interacting part of this dimer and, as indicated in Fig. 1c, was placed nearby the bridge position of the Pt cluster prior to the geometry optimization calculation.

4. Results and discussion

4.1 1-Protonated, unprotonated and neutral forms of the L-Cys and L-Cys₂ systems

By exploring the L-Cys adsorption at the sites T, B, F and H of the Pt surface, we found that the radical form of the L-Cys molecule adsorbs preferably at the bridge position (B site) on the Pt surface. From now on, the explored forms of L-Cys adsorbed on this site will be referred as L-CysB. Protonated (p-L-CysB), neutral (n-L-CysB) and unprotonated (u-L-CysB) structures were explored.

For each one of these, two different conformations were analysed. The first conformation presents the carboxylate moiety close to the surface and the second one shows the carboxylic group away from the surface, they are identified by the letters c and a, respectively. Fig. 2 shows all these optimized structures. For the protonated system, p-L-CysB, only one conformation was found as a minimum in the explored potential energy surface. The attempt to identify a p-L-CysB conformation with the carboxylic group away from the surface lead to the same structure that the optimization with the carboxylic group near the surface.

For the unprotonated conformations of L-Cys, u-L-CysB-a and u-L-CysB-c, the u-L-CysB-a system is lower in energy than u-L-CysB-c by approximately 22.6 kcal mol⁻¹. In Fig. 2, it can be observed that this former conformation allows both the NH₂ and COO⁻ groups to interact with the Pt surface, which explains such stabilization. However, for the neutral structures n-L-CysB-a and n-L-CysB-c, the conformation with both functional groups

Fig. 2 Optimized structures of the protonated (p-L-CysB), neutral (n-L-CysB) and unprotonated (u-L-CysB) cysteine conformations in which the carboxylic moiety is close to the surface (structures c) and those with the carboxylic group located away from the surface (structures a). For the p-L-CysB system, a single minimum was found in the explored potential energy surface; such structure shows the COOH group next to the surface.

close to the metal surface does not provide the same stabilization. The system n-L-CysB-c, in which the COO⁻ moiety interacts better with the surface, is lower in energy by 20.7 kcal mol⁻¹ than n-L-CysB-a. By comparing n-L-CysB-a and u-L-CysB-a, in Fig. 2, it can be noted that the protonated NH₃⁺ group in n-L-CysB-a does not interact in the same way with the surface as does the NH₂ group in u-L-CysB-a. The protonated p-L-CysB system, as shown in Fig. 2, adopts a structure where the COOH group is closer to the metal surface.

The theoretical results are supported by the IR spectra shown in Fig. 3, where the L-Cys adsorption on the Pt surface was accomplished over a range of pH values.

Table 1 lists the computed vibrational frequencies and the assignments of the structures presented in Fig. 2 and the observed vibrational bands related to the adsorbed L-Cys at different pH values, as shown in Fig. 3.

According to the data in Table 1 and the IR spectra in Fig. 3A, the bands related to the carboxylic group are more prominent at pH 0, while the N-H bending mode is not observed. Therefore, the p-L-CysB structure, which was also predicted by borrowing the SERS⁴¹ technique, is supported. The p-L-CysB system, however, is distinct from previous proposals related to Au^{19,20} and Ag^{13,15,16} experiments performed in similar conditions. These last surfaces are protonated systems with the amino group closer to the surface. Such a difference is based on the high affinity of the Pt electrode for H atoms, which are more acidic while bonding to the O atom than the N atom.

The carboxylic acid group is deprotonated ($pK_{a_1} = 1.71$)⁴² as the pH increases. The IR spectra in Fig. 3A show the appearance of bands related to the amine group (960–1008, 1460–1550 cm⁻¹) together with the intensity diminution of carboxylate bands (1213–1290, 1570–1613, 1545–1580 cm⁻¹). Spectra taken at pH 3 and 7 show the similar bands, but the spectrum taken at pH 7 is significantly more intense than that at pH 3. The band observed in the pH 0 spectrum at 1213 cm⁻¹ and attributed to the vibration related to carboxyl-H-Pt group can also be observed at pH 3 and 7 but as an enlargement of the band located between 1160 and 1270 cm⁻¹ for pH 3 and a single band at 1290 cm⁻¹ at pH 7. This shift in wavenumber can be related to differences in the force constant of the vibrations. The calculations indicated a shift in the opposite direction but, it must be noted that the calculations did not consider the contribution of H_(ads) derived from the solution, just from L-Cys. This species can interfere with the spectra in two ways, one as a competitive adsorption, what justify the low intensity of the spectrum at pH 3, and because of the lower H⁺ concentration at pH 7, it allows a higher adsorption of L-Cys. The second way would be as the possibility of carboxyl-H-Pt group interaction, even when the L-Cys in solution is already deprotonated, and making possible the observation of the vibration of this group closer than the calculated to p-L-CysB than to n-L-CysB-a or -c.

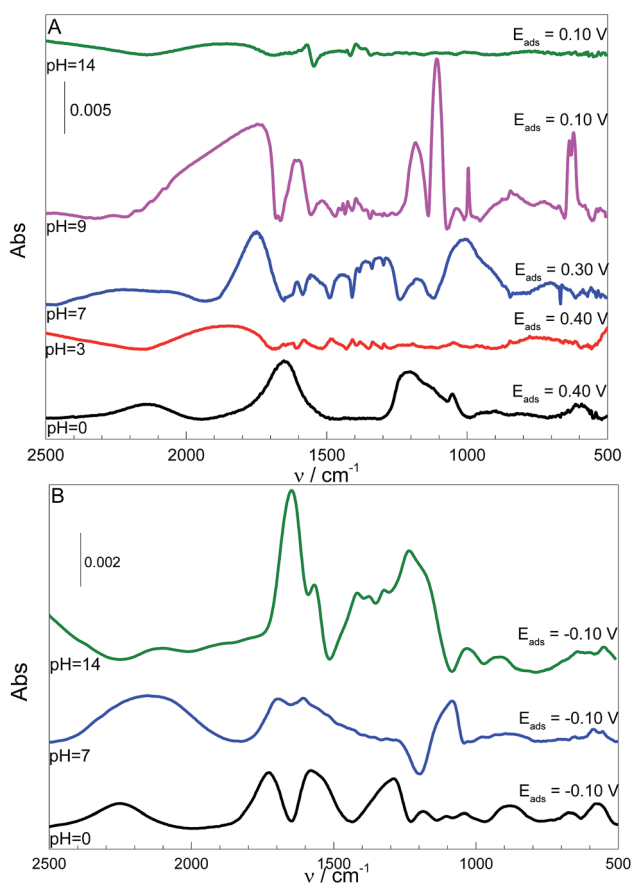

Fig. 3 IR spectra obtained for the adsorption of L-Cys (0.10 mol L⁻¹) (A) and L-Cys₂ (sat) (B) at different pH values. The adsorption potential, E_{ads} , for each pH is given at the right-hand side of each spectrum.

$\nu_{C=O}$	1682	1660	1674			1613	1606	1570
$\nu_{COO(assym)}$			1674		1580	1545		

The n-L-CysB-c calculated structure, which has lower energy, can explain the experimental results better than n-L-CysB-a since the former indicates a higher presence of horizontal vibrations, that could not be observed in a surface spectroscopic technique.^{43,44} All adsorption procedures were performed at open circuit potential (ocp), due to the spontaneity of the thiol adsorption. The difference between their ocp values is not very important ($\Delta E = 0.10$ V), and can be related with the shift of the potential window of the electrode due the pH variation ($\Delta E \cong 0.10$ V, estimated by Nernst equation).

At pH 9, with the thiol group is deprotonated ($pK_{a_2} = 8.53$,⁴² meaning $3[\text{thiolate}]/[\text{thiol}]$), the spectrum is quite different. It is already known that the nucleophilic character of the thiolate species is higher than the protonated one, and the ocp value changes ($\Delta E = 0.30$ V) to a higher extent than the shift observed at pH 0; thus, the deprotonation could also justify a higher affinity between the thiolate species and the surface. The observed bands can be explained by a structure similar to n-L-CysB-c, which is quite expected. Since the protonation states of the carboxyl and amino groups remain the same, the only possible difference between these two situations could be that at pH 9 the molecule can be more twisted, positioning the carboxylate closer to the surface, and consequently more vertical, leading to the increase of carboxyl related bands observed at this condition. This twisted geometry makes sense if one takes into consideration the activity increase of the starting molecule, a fact that due the Frumkin model behaviour of adsorption,^{9,41} would be followed by some rearrangement of the adsorbed species, making possible to decrease the repulsion between adsorbed and solution species, allowing a higher surface coverage.

At pH 14, L-Cys is fully deprotonated ($pK_{a_3} = 10.36$),⁴² the u-L-CysB-a and u-L-CysB-c systems should provide a realistic picture of the structures adsorbed on the Pt surface. At this pH, the coverage of the surface should be low since the absorbance is much lower than for the other pH values. Additionally, at this condition, the contribution of COO^- almost vanished; thus, a structure with the $-\text{NH}_2$ closer to the surface and a laid-down carboxyl can be expected. Additionally, this kind of behaviour can be expected for structures similar to u-L-CysB-a.

Others bands can be observed, at 1054, 1047, 1178 and 1040 cm^{-1} , from pH 0 to 9, could be related to sulphate (SO_4^{2-}) stretching bands. Additionally, the ones at 1653, 1850, 1749, 1753 and 1856 cm^{-1} , from pH 0 to 14, must be related to water bending. That appears even with the background subtraction, due to a rearrangement of water molecules close to the electrode surface, resulting in changes in its intensity due the surface spectroscopy selection rules.^{43,44}

Focusing on L-Cys₂ species, a similar analysis was performed. The DFT/PBE-D3/def2-SVP/COSMO (water) optimizations carried out for the L-Cys₂ system, as described in Section 3.2 and shown in Fig. 1. Fig. 3B shows the IR spectra for the L-Cys₂ adsorption. According to Watanabe's work,¹² species containing a Pt-S(R)-S-R moiety are expected in this kind of experiment. However, the current calculations and IR spectra suggest that the adsorption can lead to dissociation of the S-S bond.

Considering the spectra displayed in Fig. 3B and the assignments given in Table 2, one can expect that the

adsorption experiment using L-Cys₂ as the reactant yields similar adsorbed structures to those shown in Fig. 2 for the L-Cys system, would be as follows: p-L-CysB for pH 0, n-L-CysB-a for pH 7 and u-L-CysB-c for pH 14. The bands related to the electrolyte were found at 888, 1085 and 1200 (negative) cm^{-1} (pH 0, 7 and 14), while the water related ones at 1728, 1700 and 1648 cm^{-1} (pH 0, 7 and 14).

The vibrational band related to the C-S bond stretching is dependent on the conformation of the adsorbed molecules (as listed in Table 1) as follows: lower frequency values should be observed for the fully protonated species, p-L-CysB, and higher ones for the neutral structure, n-L-Cys-c. For all pH values, the observed band was found to be large and the band is displaced to higher wavenumbers in alkaline media. The contribution of the amino group vibrations also becomes more important under these conditions. This pattern is observed for experiments using both L-Cys and L-Cys₂.

4.2 Electrooxidation and oxidized L-Cys structures

Following the adsorption procedure, the potential was switched to more positive values with each spectrum taken after the current reached a constant value. In the sequence, the electrochemical system was turned off and the working electrode was inserted in a piranha solution during 20 min for chemical cleaning. At the same time, the electrolytic solution was purged with N₂. To observe spectra corresponding to more positive potentials, the adsorption procedure was repeated, followed by the application of a more positive potential, and then the spectra were recorded. The adsorption spectra were subtracted from those taken at different potentials. Fig. 4 shows a set of these spectra for the systems using L-Cys (A) and L-Cys₂ (B) as reactants, obtained at pH 7. Results obtained at other pH values are given as ESI.†

The experiments conducted with systems A and B indicate that the beginning of the oxidation is followed by the decrease of the SO_4^{2-} band (approximately 1100 cm^{-1}), that became a negative band, and the rise of the well-known HSO_4^- bands (approximately 1000 and 1250 cm^{-1}). The presence of this species can be explained by the oxidation of the organic molecules at the surface of the electrode and this process would generate H⁺ in the interface, responsible for the decrease of the interfacial pH and the

generation of HSO_4^- . This behaviour started approximately 0.60 and 0.70 V, depending on the pH, for both molecules, which is in agreement with that expected from the literature for the beginning of the oxidation of these molecules.⁹

Fig. 4 also shows bands approximately 2300 cm^{-1} for the highest potential applied that can be related to the presence of CO_2 . It is worth mentioning that after each applied oxidation potential the system was purged, just to assure the absence of

any significant amount of CO_2 . This procedure is quite efficient since all experiments were performed until the same final time and those bands were not observed at more negative potentials, suggesting that this time is not enough to obtain CO_2 transported to the pathlength. The fact that this band only appears at high potentials, combined with the decrease of $-\text{COO}^-$ bands, that become negative bands in some cases, indicates that the adsorbed molecules are decarboxylated *via* a Kolbe reaction;^{45,46} this process can be observed for the oxidation of oxygenated molecules at high overpotentials. This side reaction is favoured under conditions where the carboxyl group is unprotonated,^{45,46} and since the pK_a of this organic function is 1.71,⁴² this is not expected to be observed at $\text{pH} = 0$. However, the CO_2 bands are present even when the carboxylate group should be protonated (spectra for acidic pH are given in the ESI†). This apparent contradiction can be reconciled if we consider the proposed adsorbed structures of p-L-CysB, given in Fig. 2. The most stable structure for adsorbed L-Cys in an acidic medium corresponds to a conformation in which the $-\text{COOH}$ group is close to the surface. The interaction between the acidic hydrogen and the electrode surface weakens the O-H bond. As the Kolbe reaction⁴⁵ proceeds by an inner sphere electron transfer, involving a $-\text{COO}-\text{M}$ bond, it would be most favourable for structures with a carboxylic group close to the surface, thus facilitating the process. These two facts can explain why this side reaction is more expressive at lower pH values. In addition, they justify the negligible formation of CO_2 at higher pH values (9 or 14).

Furthermore, we carried out DFT/PBE-D3/def2-SVP/COSMO (water) calculations of potentially oxidized structures of the adsorbed L-Cys. Oxidized structures of u-L-CysB-a, n-L-CysB-c and p-L-CysB were investigated; the optimized structures are shown in Fig. 5. We noted that u-L-CysB-a and n-L-CysB-c are the most stable forms of u-L-CysB and n-L-CysB conformations, while for the p-L-CysB species only one minimum was found. Two different adsorbed oxidized forms were considered for u-L-CysB-a, n-L-CysB-c and p-L-CysB species as follows: the adsorbed sulfoxide (Ox1) and sulfone (Ox2) structures.

Guided by the experimental evidence present in the current investigation, the desorbed species, sulfenic acid (a), sulfoxide

Fig. 6 Optimized structures of desorbed oxidized species considered in the current investigation: sulfoxide (d), sulfone (j), sulfenic acid (f), sulfinic acid (g), and sulfonic acid (i).

(b), sulfinic acid (c), sulfone (d) and sulfonic acid (e) were also explored at the DFT/PBE-D3/def2-SVP/COSMO (water) level of theory. Their optimized geometries are presented in Fig. 6.

The identification of the oxidized species followed the same strategy applied for the adsorbed structures; the experimental bands were compared with the calculated ones. Based on our experimental evidence, Table 3 lists the free and adsorbed organic species that are assumed to be present, their calculated vibrational frequencies, their experimental ones and the experimental conditions in which they were found (pH and potential).

The existence of desorbed species in acidic media at potentials more positive than 0.80 V was already proposed in an earlier publication.⁴¹ Based on the results presented in Table 3,

the assumption of potentially free species is quite feasible. It is possible to verify that the groups related to desorbed oxidized species were found only at more positive potentials at acid media. This behaviour is also observed under other pH conditions.

Considering the species detected by the spectroscopic measurements (Fig. 4, Table 3) and the DFT results presented during the previously sections, the mechanism in Scheme 2 is presented. Some of the species listed in Scheme 2, such as the adsorbed sulfone, were previously mentioned in the literature² but without any spectroscopic evidence.

From Table 3, it can be inferred that bands that can be related to sulfoxide groups are present using both reactants when the pH was high. The thiol S–H bond is not expected to be observed at such alkaline pH values; thus, a functionality, such as sulfoxide, that presents an oxygen atom also bonded to the sulfur and is expected to be more acidic; therefore, it would be more likely to observe other species that are known to be more stable,⁴⁷ such as sulfenic acid (f), but only one band that could be related to the SOH angular deformation was observed (846 cm^{-1} at 0.80 V and pH 3, 845 cm^{-1} at 0.70 V and 836 cm^{-1} at 0.90 V at pH 7, 839 cm^{-1} at both 0.70 and 0.90 V at pH 9). The f species can be formed from sulfoxide (d) by isomerization (Scheme 2), but as *ex situ* techniques are not able to detect such systems, its disproportionation is more likely. Only one band is observed that would be related to f instead of two bands, as presented in Table 3. This acid was already suggested as an intermediate by Oliveira-Brett⁵ but using a different system. Another suggested intermediate is the sulfinic acid (g), which could be related to one band (1135 cm^{-1} at 1.00 V and 1140

Table 3 Assignment of the infrared electrooxidation spectra of L-Cys and L-Cys₂. The molecule and molecular vibration associated to each band are given in the first two columns. The calculated and observed frequencies are given in the third and fourth columns, respectively. The last two columns indicate the experimental conditions for the observed spectra, pH and potential (*E*, vs. Ag/AgCl KCl_{sat})

Molecule	Assignment	Calculated frequencies/cm ⁻¹	Observed frequencies/cm ⁻¹	pH	<i>E</i> /V	Reactant
p-L-CysB	$\nu_{\text{C-S}}$	595–644	535–648	0	All	L-Cys ₂

Scheme 2 Proposed mechanism for L-Cys and L-Cys₂ oxidation on a Pt electrode. Potential and pH conditions at which the species were detected are also depicted. When only potential is mentioned, the functional group was present under all pH conditions.

cm^{-1} at 1.20 V at pH 0, 1130 cm^{-1} at 1.10 V and pH 7, related to ν_{SOH} and 1010 cm^{-1} at 0.70 V and pH 14, related to $\nu_{\text{S=O}}$).

Each step presented in Scheme 2 is followed by the potential applied to the system when the bands started to be noticed; in the cases where some bands were found only under special pH conditions, those are also highlighted. Consequences of this procedure are empirical suggestions regarding to the energetics of each step. Steps 3i, 3ii and 3iii are expected to be in competition. The generation of sulfoxide, possibly related to three bands at pH 14 and more probable to occur at this condition, can be found in competition with the sulfenic acid and the adsorbed sulfoxide. The sulfenic acid is more stable than the sulfoxide as already stated, and they can also be involved in the equilibrium of isomerization (4ii). The adsorbed sulfoxide was frequently found in these measurements; therefore, 3ii is expected to be always present, while the others apparently only appear at specified pH conditions.

Other steps that would compete are 6i and 6ii, both of which involve oxidized adsorbed sulfoxide species. Step 6i seems to be

less effective than 6ii since the bands assumed to be related to adsorbed sulfone are observed over 0.80 V in all pH values.

The desorbed sulfone, suggested for a Pd electrocatalyst¹⁰ was not detected in the Pt electrode studies.

The presence of a band assigned to the thiol function vibration ($\nu_{\text{S-H}}$ expected to be at 915 cm^{-1}) was found at almost all pH values for the system with the L-Cys₂ (893 cm^{-1} region) as a reactant, suggesting that even when the dimer is used as a starting molecule, a desorbed monomeric molecule can be generated. This is probably due to the low concentration observed in the L-Cys₂ case, inducing a low coverage degree of the surface and making it less possible to observe redimerization. One may expect that since the starting molecule was a dimer,⁴⁸ both adsorption sites should be really close, but some have suggested that this is not a one step process, it can be an oxidation followed by a reduction process.⁴⁸ Thus, some species can be adsorbed in sites that are not very close to each other and consequently, not be involved in the desorption process at the same time.

5. Conclusions

The interaction of L-cysteine and its dimer, L-Cys₂, with a platinum electrode and their oxidation products were explored experimentally and theoretically. Using DFT calculations, the most stable adsorbed conformations for the different protonation states were predicted and supported by IRRAS. This experimental approach allowed a study of the adsorption for both molecules under different pH conditions, a variable that strongly influences the adsorption potential of the molecule.

The joint exploration encompassing the DFT and IR spectra (IRRAS technique) investigations for the oxidation process of these amino acids lead us to propose a new and more complex mechanism.
