Urchin-like CoO–C micro/nano hierarchical structures as high performance anode materials for Li-ion batteries†

Lili Liu,^a Lihui Mou,^a Jia Yu^{bc} and Shimou Chen^{*b}

In this work, urchin-like microspheres consisting of radial carbon-coated cobalt monoxide nanowires are designed, to fabricate a micro/nano hierarchical structure for efficient Li-storage. A sequential conversion process is adopted, involving hydrothermal synthesis of an urchin-like cobalt carbonate hydroxide precursor, glycosidation of glucose as a coating layer, and calcination in an inert atmosphere to form a CoO–C composite. On the one hand, the CoO framework provides a high Li-storage capacity with short transport paths and ordered free spaces. On the other hand, the carbon coating layer buffers the volume expansion of inner active materials during lithiation, while providing a stabilized electrode/electrolyte interface and rapid electronic conduction. When tested as an anode material for lithium ion batteries, the urchin-like CoO–C delivers a reversible capacity of 755 mA h g⁻¹ after 100 cycles. With rate increasing, the performance advantage of the CoO–C composite electrode over a single CoO electrode is obvious.

Introduction

One key factor that has impeded the improvement of lithium ion batteries (LIBs) is the limited performance of the present electrode materials, which hardly satisfies the increasing demand of high energy & power density and long-term stability. Fabricating composite nanostructure electrodes becomes a frontier issue due to the synergistic effect imparted by multiple compositions.^{1–3} As promising next-generation anode materials, transition metal oxides (MO_x, M = Co, Ni, Cu, *etc.*) exhibit high theoretical capacities, because of their unique conversion mechanism (MO_x + 2xLi⁺ + 2xe⁻ ↔ M + xLi₂O).^{4–6} For example, cobalt monoxide (CoO) delivers a high theoretical capacity of 715 mA h g⁻¹, almost twice that of a commercial graphite anode. However, CoO also suffers from serious drawbacks as LIB anodes, such as large expansion during lithiation process, repeated formation of solid electrolyte interface (SEI) film and slow Li⁺ and electron diffusion, thus leading to poor rate capability and cycling stability.^{4,7} Up to now, several strategies have been adopted to address above issues, among which compositing and nanostructuring are two main methods to improve Li-storage capability.^{8–11}

On the one hand, electrochemically stable coatings layers like carbon, can prevent a direct contact between CoO and electrolyte, and improve the originally poor electric conduction.^{12,13} Moreover, carbon coating can also buffer the stress imparted by volume expansion of inner active materials during cycles, thus leading to improved rate capability and cycling performance. For example, nitrogen-doped carbon-wrapped porous CoO nanocubes showed a reversible capacity of about 600 mA h g⁻¹ as LIB anode material.¹⁴ And carbon-coated CoO wall arrays on Ni foam also exhibited excellent lithium storage performance.¹⁵ Among them, thermal decomposition using low-cost glucose precursor is a well-established and applicable carbon coating method for large-scale production.^{16,17} On the other hand, fabricating 3D nanostructures with short transport paths and ordered free space is another effective strategy, such as nanoarrays, nanonets and nanowire clusters.^{7,10,11} For example, ultrathin CoO nanosheet arrays fabricated *via* galvanostatic electrodeposition achieved a capacity of about 1000 mA h g⁻¹ as a LIB anode.¹⁰ Particularly, microspheres composing of nanowires which fanned out, were able to relieve the volume variation stress during cycles, as well as provide a short ion transport pathway. As another cobalt-based oxide, pompon-like hierarchical Co₃O₄ microspheres were able to show superior Li-storage performance compared with nanoparticles and nanowires, proving great potential in LIB anode applications.¹⁸ Therefore, it is reasonable to combine 3D hierarchical microsphere architecture with carbon coating layer, for achieving further improved electrochemical performance.

In this work, an urchin-like CoO–C composite structure with micro/nano hierarchical structure was proposed and synthesized *via* a sequential conversion procedure (Scheme 1).

Scheme 1 The sequential conversion procedure for constructing urchin-like CoO–C micro/nano hierarchical structure: (a) urchin-like cobalt carbonate hydroxide precursors prepared via one-pot hydrothermal synthesis. (b) Glycosidation of glucose on precursors via second hydrothermal synthesis. (c) Final CoO–C prepared after calcination in inert atmosphere. (Left bottom: simulation diagram of the lithium ion battery with urchin-like CoO–C as the anode).

Specifically, the preparation process included one-pot hydrothermal synthesis of urchin-like cobalt carbonate hydroxide precursors (Scheme 1a), subsequent coating process using glycosidation of glucose via second hydrothermal synthesis, and final calcination process in inert atmosphere to obtain CoO–C. The inner radial CoO nanowires can provide a high capacity and stable Li-storage framework, because of the conversion mechanism, short transport paths and ordered free space. Meanwhile, the external amorphous carbon coating layer provides stabilized electrode/electrolyte interface and enhanced electronic conduction and also alleviate the volume expansion of inner active materials during lithiation process. Therefore, such composite micro/nano hierarchical design was able to efficiently integrate advantages and circumvent drawbacks of the two different compositions, to form a synergistic Li storage system.¹⁹ It's worth noting that using glucose as the thermal decomposition precursor to fabricate the carbon coating layer is a low-cost and efficient technique, while other routines may suffer from a high cost (chemical vapor deposition or magnetothermal reduction) or a poor electrochemical interface (*ex situ* mixing). When applied in LIB anode materials, benefiting from its unique compositional and structural characteristics, this synergistic nanostructured design has great potential in enhancing the Li-storage capability of transition metal oxides, especially for high rate charge/discharge.

Experimental

Preparation methods

All of the chemicals were analytical grade and were used without further purification. During a typical experiment, firstly 20 mmol of cobalt nitrate hexahydrate ($\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$) and 5 mmole of urea ($\text{CO}(\text{NH}_2)_2$) were dissolved in 40 mL of deionized water, and then the solution was transferred into a 50 mL Teflon-lined

autoclave. After 5 h of hydrothermal reaction at 180 °C, the obtained hydrothermal products was rinsed by deionized water and ethanol for several times, and then dried at 80 °C. Subsequently, 0.2 g of above hydrothermal product powders and 2 mmol of glucose (or 4 mmol for comparison) were heated under 180 °C for 3 h (or 8 h for comparison) to conduct second hydrothermal process. Finally, after rinsing and drying, products of the second hydrothermal reaction were calcined at 500 °C for 3 h in nitrogen atmosphere, to obtain the urchin-like CoO–C micro/nano hierarchical composite. As a contrast, single CoO microspheres were prepared under similar reaction system and conditions, except that the second hydrothermal process was omitted.

Characterizations

Scanning electron microscopy (SEM) and high resolution scanning electron microscope (HRSEM) observations were carried out on the SU8020 microscope (Hitachi). Energy dispersive spectroscopy (EDS) analyses were performed using an Oxford X-MaxN attached to the Hitachi SU8020 at 20.0 kV, with a silicon slice as the substrate. Transmission electron microscopy (TEM) and high resolution transmission electron microscope (HRTEM) observations were performed with the JEM-2100F microscope (JEOL). Raman spectra were recorded using the LabRAM HR800 514 nm Ar-ion laser (Horiba Jobin-Yvon). X-ray diffraction (XRD) patterns were recorded using a Bruker D8 Focus X-ray diffractometer equipped with a Ni-filtered Cu-K α radiation ($\lambda = 0.15406$ nm) source. X-ray photoelectron spectroscopy (XPS) data were obtained with the ESCALAB 250Xi (Thermo Fisher Scientific) using a monochromated Al-K α X-ray source. Thermo gravimetric (TG) analysis was performed using the STA7200RV (Hitachi High-Tech), with nitrogen atmosphere and a heating rate of 5 °C min^{-1} . The specific surface area and pore volume were measured by the N_2 adsorption/desorption isotherm method on a Quadasorb SI-MP analyzer.

Electrochemical measurements

Electrochemical measurements were performed at room temperature using coin-type half-cells. The CoO–C (or CoO), super P and polyvinylidene fluoride (PVDF) were mixed with a weight ratio of 80 : 10 : 10 using 1-methyl-2-pyrrolidinone as the solvent, followed by pasted onto copper foil and dried at 80 °C. The active material mass was determined according to the weight difference between the electrode piece and bare copper foil piece. The loading mass for each electrode piece was about 3.2 mg. Lithium foils were used as counter electrodes. And Celgard 2400 membranes were used to separate the working electrode and counter electrode. The electrolyte was 1 mol L⁻¹ of LiPF₆ in EC/DEC/DMC mixture (1 : 1 : 1 in weight). To cycle coin cells, they were discharged to 0.01 V (*vs.* Li/Li⁺) and charged to 3.0 V (*vs.* Li/Li⁺) on the LAND battery testing system. Cyclic voltammetry (CV) data was recorded on the Autolab (PGSTAT302N) electrochemical workstation, with a scanning rate of 0.1 mV s⁻¹ and a voltage range of 0.01–3.0 V. Electrochemical impedance spectroscopy (EIS) measurements were carried out on the ACM Gill-AC-4 electrochemical station.

Results and discussion

Morphology characterizations

The morphologies of precursors and final products were investigated by SEM and HRSEM, to observe the constructing process of micro/nano hierarchical structure. In Fig. 1a and S1 (ESI[†]), cobalt carbonate hydroxide precursors obtained after the first hydrothermal process exhibited an uniform urchin-like microsphere structure with diameters of 5–10 μm. The nanowire basic units fanned out from the core, exhibiting diameters of 20–40 nm with relatively smooth surface (Fig. 1b). After second hydrothermal and calcination processes, CoO–C microspheres maintained a consistent structure with precursors (Fig. 1c and S2[†]).

The carbon-coating CoO nanowires acted as basic units to fabricate into an urchin-like microsphere, forming a unique micro/nano hierarchical structure. Meanwhile, it was observed that the radial nanowires exhibited slightly increased diameters of 30–50 nm, accompanying with relatively coarse surface due to calcination treatment (Fig. 1d). In addition, a more obvious carbon coating layer was observed when the glucose amount and reaction time of the second hydrothermal process were increased, because of the higher coating amount. However, the original urchin-like morphology could hardly be maintained, with the nanowire basic units becoming twisted and coarser (Fig. S3[†]).

The microstructure of the CoO–C composite microsphere was further observed by TEM and HRTEM. Fig. 2a and b clearly demonstrated the unique micro/nano hierarchical structure. Fig. 2c exhibited the porous structure of the nanowire basic unit, which might result from the gas releasing during calcination.²⁰ This could provide better access for Li⁺, and shorten diffusion paths of Li⁺ and electrons, thus benefiting the rate capability.^{21,22} In addition, a thin light-color coating layer was observed, which corresponded to the amorphous carbon coating layer. This might enable extra interfacial lithium storage, which was favorable to the energy density of this composite system.²³ From the TEM observations (Fig. 2c and S4[†]), the thickness of the carbon coating layer was about 3–6 nm. As shown in the HRTEM image of an individual CoO–C nanowire (Fig. 2d), two interplanar spacings of 0.21 and 0.25 nm were clearly observed, which resulted from CoO (200) and (111) lattice planes respectively, indicating the polycrystalline nature.²⁴

Compositional and structural characterizations

The thermal behaviour of the precursor (Co(CO₃)_{0.5}(OH)·0.11H₂O) in nitrogen atmosphere was investigated by TG analysis (Fig. S5a[†]). It was observed that a major thermal event took place at around 300 °C during the heating process. The total

Fig. 1 Product morphologies at various synthesis stages: (a, and b) urchin-like cobalt carbonate hydroxide precursor microspheres, with diameters of 5–10 μm and relatively smooth surface. (c and d) Final CoO–C microspheres, their radial nanowire basic units exhibiting relatively coarse surface. Insets: corresponding simulation diagrams.

Fig. 2 (a and b) TEM images of the CoO–C micro/nano hierarchical structure. (c) TEM image of the individual nanowire, exhibiting the porous structure of inner CoO and the thin carbon coating layer. (d) HRTEM image exhibiting the (200) and (111) lattice planes of CoO.

weight loss is about 28.4% above 300 °C, because of the decomposition of precursor into CoO, CO₂ and H₂O in the N₂ atmosphere. This value is slightly smaller than the theoretical value (30.5%), which maybe due to partial loss of H₂O in the precursor crystal structure or partial surface oxidation of CoO. To prove the product composition of EDS element mapping was carried out and clearly showed the existence of Co, O and C, confirming the CoO–C configuration profile (Fig. 3). In addition, basing on the TG data of the CoO–C composite in nitrogen atmosphere (Fig. S5b†), the weight percentage of carbon component was less than 5%. It indicated a thin carbon coating layer, which agreed with the SEM and TEM observations.

Subsequently, the product crystalline structures investigated by XRD at various synthesis stages clearly prove the successful fabrication of CoO–C. For the precursor, all the identified peaks can be assigned to pure orthorhombic Co(CO₃)_{0.5}(OH)·0.11H₂O (JCPDS card no. 48-0083, space group: *P22₁2*) (Fig. 4a).²⁵ For the XRD pattern of final composite material, five obvious diffraction peaks coinciding with the (111), (200), (220), (311) and (222) planes of standard spectrum of face-centered cubic CoO (JCPDS no. 78-0431, space group: *Fm3m* (225)) (Fig. 4b).¹⁵ The sharp peaks indicated high crystallinity and relatively large crystallite size, which agreed with above TEM results.²⁶ Meanwhile, the broad peak around 20° indicated the coating of amorphous carbon layer.¹⁶ As a comparison, the single CoO sample without carbon coating process showed a similar XRD pattern except for the broad peak corresponding to carbon (Fig. S6†). In addition, the Raman spectrum in the range of 50–1200 cm⁻¹ showed two characteristic peaks of CoO at 190 and 517 cm⁻¹ which could be attributed to the F_{2g} mode. Meanwhile the other two peaks at 471 and 678 cm⁻¹ corresponded to the E_g and A_{1g} modes, respectively. (Fig. S7†).⁹ To investigate the porous characteristic of the CoO–C sample, we show the N₂ adsorption-desorption isotherm and pore-size distributions in Fig. 4c and d, respectively. According to the IUPAC classification, the shape of the hysteresis loop was ascribed to type H3.²⁷ The average pore size was about 13 nm, and the mesoporous urchin-like CoO–O showed a high BET surface area of 76 m² g⁻¹.

Fig. 3 EDS element mapping of the urchin-like CoO–C microspheres, confirming the existence of Co, O and C.

Fig. 4 (a and b) XRD patterns of the Co(CO₃)_{0.5}(OH)·0.11H₂O precursor and CoO–C composite material respectively. (c) N₂ adsorption-desorption isotherm and (d) pore-size distribution curve of the urchin-like CoO–O.

Therefore, it was expected that the as-prepared mesoporous CoO–O microspheres would possess an excellent Li storage performance.²⁸

XPS characterization was used to further clarify chemical compositions. As shown in Fig. 5a, the full-survey spectrum clarified the presence of Co, O and C elements, verifying the successful fabrication of CoO–C. For the Co 2p state, two characteristic peaks including the Co 2p_{3/2} states around 780.0 eV and the Co 2p_{1/2} states around 795.5 eV were observed, corresponding to the standard CoO composition (Fig. 5b). The presence of two prominent satellite peaks at 786.4 and 803.0 eV further suggested the formation of the CoO phase after the calcination process in inert atmosphere.²⁹ Fig. 5c displayed the C 1s peak, which corresponded to the carbon layers in the CoO–

Fig. 5 (a) Full-survey, (b) Co 2p, (c) C 1s and (d) O 1s states XPS characterizations of the CoO–O, further evidencing its chemical compositions.

C. There were no obvious peaks existed around binding energies of 281 and 283 eV, indicating that carbon was not doped into the CoO phase.¹⁵ For the O 1s state, it was obvious that the O 1s XPS spectra can be deconvoluted into two sub-peaks (Fig. 5d). The peaks located at 530.0 was assigned to O bond in CoO crystalline networks, while the other smaller peaks around 531.8 eV can be assigned to the weakly absorbed surface hydroxyl and structural water.³⁰

Lithium storage performances

As-prepared urchin-like CoO-C micro/nano hierarchical structures were evaluated as LIB anode material to investigate its Li-storage potential. Fig. 6a showed 1st, 30th and 50th charge/discharge voltage *vs.* capacity curves at a current density of 100 mA g⁻¹ and a voltage range of 0.01–3.0 V (*vs.* Li/Li⁺), which was consistent with the electrode composition units. A broad plateau starting around 0.8 V followed by a downward sloping was observed in the first discharge curve, which shifted to higher voltage and became less well-defined in the subsequent cycles. The plateau corresponded to the lithium storage in CoO, and the slope can mainly be ascribed to the interaction of Co with the electrolyte to form SEI film.^{10,31} The lower initial discharge plateau which differed from subsequent cycles could be attributed to the irreversible reactions and complex phase transformation of CoO to Co.^{7,32} The initial discharge and charge capacities was 1207 and 919 mA h g⁻¹. Being much higher than the theoretical capacity of 715 mA h g⁻¹ for CoO, the extra discharge capacity was mainly attributed to the electrolyte decomposition process which consumed Li⁺ and formed the SEI film.³³ Meanwhile, the irreversible capacity loss of ~300 mA h g⁻¹ was attributed to the incomplete decomposition of SEI

and Li₂O, accompanying with other factors including kinetic limitations.³⁴ However, when compared with usual conversion-type anodes, the initial coulombic efficiency of 76% was relatively high, mainly owing to the carbon coating layer which introduce a stabilized electrode/electrolyte interface.^{12,13} And well capacity retention was observed in subsequent cycles.

As this metal oxide-carbon synergistic system was expected to exhibit considerable performance advantages than single-composition metal oxide anode, therefore special capacity and cycling stability of the CoO-C microspheres were comprehensively compared with the CoO with similar structure and without the carbon coating layer, in the voltage range of 0.01 V to 3.0 V *versus* Li/Li⁺. Fig. 6b highlighted that the introduction of carbon would decrease the special capacity in initial several cycles, however carbon could efficiently enhance the electrode capacity retention in subsequent cycles. The CoO-C was able to maintain a discharge capacity as high as 755 mA h g⁻¹, after 100 cycles at a current density of 100 mA g⁻¹, indicating 80% retention of second discharge capacity. By contrast, that of the solely CoO was only 573 mA h g⁻¹, with only 56% retention of second discharge capacity. In addition, the CoO-C exhibited a coulombic efficiency of above 99% except for first several cycles, being slightly higher than that of the CoO electrode (Fig. S8a†). When the current density was increased to 500 mA g⁻¹, the CoO-C still maintained a discharge capacity of 667 mA h g⁻¹ after 200 cycles with a high coulombic efficiency (Fig. 6c and S8b†). Meanwhile the solely CoO electrode underwent an intensified fading, and finally exhibited a discharge capacity less than half of the capacity of CoO-C. It was found that the advantage of carbon-coating treatment was more obvious in higher rate and longer-term cycles. The higher capacity retention of the CoO-C can be attributed to the

Fig. 6 (a) 1st, 30th and 50th charge/discharge curves of the CoO-C at a current density of 100 mA g⁻¹. (b) Charge/discharge capacities *vs.* cycle numbers of CoO-C and single CoO at a current density of 100 mA g⁻¹. (c) Charge/discharge capacities *vs.* cycle numbers of two electrodes at a current density of 500 mA g⁻¹. (d) Discharge capacities *vs.* cycle numbers of two electrodes at various current densities (mA g⁻¹). (e) First 5 cycles of the CV curves for the CoO-C at a scan rate of 0.1 mV s⁻¹. (f) Impedance spectra of the CoO-C electrode before and after 10 cycles.

fabrication of carbon coating layer on the CoO nanowires, which buffers the volume variation and enhances the electronic conduction.

Discharge capacities at various current densities were further compared. It was observed that capacities of both electrodes decreased monotonically as the rate increased, while the CoO-C exhibited a much higher capacity at higher rate (Fig. 6d). When tested at a high rate of 1000 mA g^{-1} , the CoO-C microspheres were able to deliver a discharge capacity of nearly 500 mA h g^{-1} . This means that the discharge or charge process could be finished in 30 min, while a capacity over that of the commercial graphite was achieved. Moreover, when the rate turned back to 100 mA g^{-1} finally, the capacity could be retained at as high as more than 800 mA h g^{-1} . As a comparison, the solely CoO faced a more dramatic fade with increasing rates, exhibiting only 350 mA h g^{-1} at 1000 mA g^{-1} .

In order to understand the electrochemical reactions during lithiation/delithiation process more explicitly, first 5 cycles of cyclic voltammetry (CV) curves for the CoO-C electrode were carried out, at a scan rate of 0.1 mV s^{-1} and a voltage range of $0.01\text{--}3.0 \text{ V}$ (Fig. 6e). The profiles were in good agreement with the Li-storage mechanism for the CoO-based anodes: $\text{CoO} + 2\text{Li}^+ + 2\text{e}^- \leftrightarrow \text{Co} + \text{Li}_2\text{O}$.³⁵ There was a sharp peak at $0.5\text{--}0.6 \text{ V}$ in the first cathodic scan, which corresponded to reduction of CoO to Co and irreversible reactions including the formation of the SEI film.^{36,37} From the second cycles, the peak had a positive shift to about 0.9 V and a decrease of density, which might be owed to the decreased surface energy of the CoO anode after the initial lithiation/delithiation process.¹⁴ In addition, cathodic peaks at lower than 0.1 V could be ascribed to the lithiation of carbon.³³ Fig. 6f showed the Nyquist impedance plots of the CoO-C electrode before and after 10 cycles, in which inclined lines at low frequency and depressed semicircles at high-medium frequency were ascribed to the lithium diffusion impedance and charge impedance respectively.¹⁸ It exhibited higher impedance after initial five cycles, which was mainly attributed to the formation of SEI film.⁸

Overall, owing to the synergistic effect from the carbon coating layer, it was observed that Li-storage performance of the original CoO could be enhanced to a great extent, especially at high rate condition. Compared with previous studies on cobalt oxide-based multiple or single component nanostructures (Table S1, ESI[†]), this CoO-C composite electrode also exhibited considerable performance advantages.^{14,15,25,38–41} The strong potential of CoO-C micro/nano hierarchical structures was attributed to several factors: (1) CoO served as high capacity Li-storage framework. (2) The nanowire basic unit provided rapid axial charge transferring and shortened diffusion path for both Li^+ and electrons which benefited the rate capability. (3) The 3D urchin-structure provided sufficient free space to buffer the volume variation which benefited the cycling stability. (4) The carbon coating layer complemented the low conductivity and volume variation issues for inner hetero-material, thus helped to obtain good capacity retention and superior performance at high rate. It also played a significant role like an artificial SEI layer to introduce stabilized electrode/electrolyte interface, without which inner active materials would be exhausted more

intensively after long-term cycles. (5) At the multi-phase interface of this hetero-structure and Co/Li₂O interface formed after the conversion reaction, there existed possible interfacial lithium storage mechanism which further enhanced the system energy density.²³

Conclusions

In summary, we have designed and constructed urchin-like CoO-C micro/nano hierarchical structures for efficient Li-storage, *via* a sequential transformation route. This preparation strategy, based on the initial hydrothermal synthesis of urchin-like cobalt carbonate hydroxide precursor, subsequent glycosidation of glucose as carbon precursor and final calcination in inert atmosphere, provided the possibility of fabricating ideal hetero-nanostructures with targeted properties. CoO basic units and carbon coating layers were fabricated into a synergistic system, and the energy & power densities of the composite CoO-C were greatly improved comparing with the single CoO, exhibiting a capacity as high as 755 mA h g^{-1} at a rate of 100 mA g^{-1} as LIB anode material. We anticipate that this work may open a low-cost and well-established avenue for the large-scale production of high performance LIB anodes based on transition metal oxides.
