Effects of macropores on reducing internal diffusion limitations in Fischer–Tropsch synthesis using a hierarchical cobalt catalyst

Hansheng Li,^{ab} Jungang Wang,^a Congbiao Chen,^a Litao Jia,^a Bo Hou^{*a} and Debao Li^a

Internal diffusion limitations in Fischer–Tropsch catalysts strongly affects their catalytic activities and product selectivities. Large pellet catalysts demonstrate especially severe internal diffusion limitations in fixed bed reactors. In order to overcome this problem, macropores were introduced into cobalt catalysts, and the resulting effects on reaction activity and selectivity were studied. Meso–macroporous silica (S1) with mesoporous walls was prepared by a sol–gel process and was used to prepare the Co/S1 catalyst. A bimodal mesoporous silica (S2) support with an equivalent mesopore diameter to the S1 support was also prepared for comparison. The effects of internal diffusion limitations in the S1 and S2 supports with different pellet sizes on FT synthesis were investigated. The results showed that the macropores played an important role in reducing internal diffusion limitations, especially for large pellet catalysts.

1 Introduction

The Fischer–Tropsch (FT) synthesis is becoming increasingly important and has attracted increasing interest in both academia and industry because of diminishing petroleum reserves, highly unstable crude oil prices, increasingly rigorous environmental regulations, and the global demand for decreased dependence on petroleum for the production of fuels and chemicals. As is known, the Fischer–Tropsch synthesis (FTS) is an indirect liquefaction process that produces high quality sulfur-free fuels and valuable chemicals from coal, natural gas, and biomass-derived syngas through steam reforming, partial oxidation, or gasification processes.^{1–4}

Among the reported FT catalysts, due to their good activities, lower activity for the competing water gas shift (WGS) reaction and high selectivity of C₅₊ hydrocarbons, supported cobalt is the preferred catalyst for CO hydrogenation to hydrocarbons in the low-temperature Fischer–Tropsch synthesis.⁵ In order to obtain high cobalt dispersion and reduce costs, cobalt is usually loaded on various supports. Unfortunately, a key challenge facing supported Co catalysts is that many fixed-bed FT reactors require large pellet catalysts (1 to 3 mm) in order to maintain the required pressure drop and heat transfer; this often leads to serious internal diffusion limitations in many applications of Fischer–Tropsch synthesis.⁶ It is known that in large pellet catalysts, very strong diffusion resistances can develop; this effect is more pronounced for CO than for H₂ because of their

different diffusion coefficients.⁷ H₂ diffuses much faster than CO; thus, the concentration of CO decreases more obviously and leads to local H₂/CO ratio increases, which often lead to high methane selectivity. Erling Rytter and co-workers⁸ found that the C₅₊ selectivity was rather constant for different pellet sizes below 400 μm, and the selectivity decreased with increasing pellet size thereafter; however, methane selectivity was exactly the opposite. Post *et al.*⁹ clearly demonstrated the effects of pellet size and pore radius on the Fischer–Tropsch activity and selectivity of CoZr/SiO₂ catalysts. They reached the conclusion that pellets in the size range normally used in industrial fixed bed reactors (1 to 3 mm) usually have serious diffusion limitations, which results in lower activity, high methane selectivity and low C₅₊ selectivity. In order to overcome this problem, several methods have been developed to reduce diffusion limitations in FT synthesis, such as using monolithic catalysts,¹⁰ using eggshell catalysts¹¹ and introducing transport pores with larger diameters. Because diffusion is assumed to be the only transport mechanism inside the catalysts, the pore size is the key parameter to optimize in order to reduce diffusion limitations and achieve good FT performance.¹² Therefore, catalysts with macropores are expected to reduce internal diffusion limitations in large pellet catalysts for fixed-bed FT reactors. Becker *et al.*¹² reported that the introduction of transport pores with large pore sizes can increase reaction rates, reduce methane selectivity and increase C₅₊ selectivity. However, catalysts with large pore sizes often have small specific surface areas; this is detrimental to the dispersion of the supported metal, leading to low metal dispersion and low catalytic activity.

^aState Key Laboratory of Coal Conversion, Institute of Coal Chemistry, Chinese Academy of Sciences, Taiyuan 030001, Shanxi, PR China. E-mail: houbo@sxicc.ac.cn

Because some aspects of catalytic property, such as dispersion, metal loading and grain size, are structurally sensitive to supports,¹³ catalysts with optimal structures should be designed in order to obtain high cobalt dispersion. Various supports for cobalt catalysts have been used in Fischer–Tropsch synthesis, including alumina, silica, zirconium, titanium and carbon supports.⁵ The structural characteristics of these supports, such as pore volume, average pore diameter, and surface area, can significantly influence the cobalt dispersion, reducibility, activity and selectivity of the cobalt catalyst for FT synthesis.¹⁴ As is known, supports with small pore sizes usually have large specific surface areas, which favors high metal dispersion, and small metal crystallite sizes. However, supports with small pores usually result in poor diffusion efficiency of the reactant and product molecules in the intra-pellet structure, leading to low activity, low C₅₊ selectivity and high methane selectivity.

Based on the above discussion, supports with hierarchical structures should have excellent advantages for addressing this contradiction because their large pores provide unimpeded channels for reactant and product molecules while their small pores simultaneously provide a large surface area; this contributes to higher dispersion of the supported cobalt crystallites. Xiaohong Zhang *et al.*¹⁵ prepared a three-dimensionally ordered macroporous (3DOM) ZrO₂ support with mesoporous walls and applied this meso–macroporous ZrO₂ as a cobalt support for FT synthesis. The cobalt catalyst supported on the 3DOM structure showed the highest reaction activity and the highest C₅₊ selectivity in the FT synthesis; this result was obtained by optimizing both the mesopores within the walls and the macropores of the 3DOM structure. Tsubaki *et al.*¹⁶ prepared bimodal porous silica by directly introducing small silica sol into large pores of silica gel; they applied this meso–macroporous silica as a cobalt support for FT synthesis. They found that the bimodal porous catalyst showed higher CO conversion than a unimodal catalyst with a small pore diameter. Meanwhile, the selectivity of the catalyst for methane was as low as that of a unimodal catalyst with a large pore diameter. They attributed the excellent Fischer–Tropsch synthesis performance to the fact that the bimodal structure not only has a high surface area but also a large pore size. Although many researchers have reported the use of materials with meso–macroporous diameters for FT synthesis, most of them used small pellet catalysts (below 300 μm) to evaluate the materials. Under these conditions, internal diffusion limitations are not present; therefore, the effects of the macropores cannot be reflected completely. D. Merino *et al.* prepared different λ-alumina supports and used them in Fischer–Tropsch synthesis (FTS) catalysts. The catalysts were tested in a lab-scale fixed-bed reactor with small (<63 μm) and large (500 to 710 μm) catalyst particle size (PS). They found that with large catalyst PS, C₅₊ selectivity decreased and CH₄ selectivity increased compared with small catalyst PS due to diffusional restrictions. However, the effects of the diffusion limitations were much lower for the catalyst obtained when the support was modified to add macropores between 100 and 1000 nm.¹⁷ T. Witoon *et al.* also obtained similar results using meso–macroporous silica-supported cobalt catalysts.¹⁸ They found that with large catalyst particles (650 to 850 μm), the C₅₊

selectivity of cobalt supported on meso–macroporous silica was much higher than that on unimodal mesoporous silica. However, in their catalysts, the macropores were not obvious and the macropore distribution was very wide.

In the present work, meso–macroporous silica with mesoporous walls was prepared by a sol–gel process with controlled phase separation and gelation kinetics; the silica was then used to prepare cobalt catalysts. The impact of internal diffusion limitations in cobalt catalysts with large pellet sizes (830 to 1700 μm) and small pellet sizes (180 to 250 μm) on catalytic activity and hydrocarbon selectivity were investigated. Moreover, in order to investigate the effects of the macropores on internal diffusion limitations in FT synthesis, cobalt catalysts (with different pellet sizes) supported on bimodal mesoporous silica with mesopore diameters equivalent to those of the hierarchical meso–macroporous silica were also prepared and used for comparison.

2 Experimental

2.1 Synthesis of supports and catalysts

Silica monoliths¹⁹ with interconnected macropores and mesoporous were prepared as follows: 1 g P123 (EO20PO70EO20, MAV = 5800, Aldrich) and 0.7 g of polyethylene glycol (PEG, average molecular weight of 10 000) was dissolved in 10 g 1 M HCl with stirring to obtain a clear solution. 5.1 g of tetramethoxysilane (TMOS) was added to the mixture; then, the mixture was stirred for 30 min in an ice bath until it became homogeneous. Then, the mixture was sealed in a plastic container and maintained at 60 °C for 24 h. The mixture was hydrothermally processed in a Teflon-lined autoclave at 100 °C for 24 h, followed by filtering and washing. The resulting wet gel was dried at room temperature for 3 days and 60 °C for 24 h and was then calcined at 550 °C for 5 h. The prepared meso–macroporous silica monoliths were ground into 10 to 20 mesh silica (noted as S1). S2 was prepared by grinding S1 into less than 200 mesh in order to destroy the macropores.

The resulting materials were used to prepare cobalt catalysts with a nominal cobalt loading of 15 wt% by an excessive impregnation method with an aqueous solution containing the cobalt(II) nitrate precursor (Co(NO₃)₂·6H₂O). Co/S1 was prepared *via* excessive impregnation using S1 as the support. Co/S1/10–20 was maintained at 10–20 mesh; Co/S1/60–80 was prepared by grinding Co/S1/10–20 into 60–80 mesh. Co/S2 was prepared *via* excessive impregnation using S2 as the support. The Co/S2 was previously tableted to obtain 60 to 80 mesh and 10 to 20 mesh samples, labeled Co/S2/60–80 and Co/S2/10–20. All the catalyst precursors were dried at 120 °C for 2 h and calcined at 400 °C in air for 6 h by increasing the temperature at a controlled heating rate of 1 °C min⁻¹.

2.2 Characterization techniques

2.2.1. Nitrogen adsorption/desorption. Nitrogen sorption was measured with an ASAP-2000 Micromeritics instrument at liquid nitrogen temperature to obtain the specific surface area, pore volume and PSD. Nitrogen isotherms were obtained in

both adsorption and desorption modes. The specific surface areas of the samples were determined by the Brunauer–Emmett–Teller (BET) method. The pore size distributions and pore volumes were obtained by applying the BJH formalism to the desorption branches of the isotherms. Before the analysis, the samples were outgassed at 120 °C for 12 h.

2.2.2. X-ray powder diffraction. Powder X-ray diffraction (XRD) was used to characterize the phase structures of the catalysts and was measured on a PANalytical Empyrean X'pert powder diffractometer operated at 50 kV and 50 mA, using monochromatized Cu K ($\lambda = 0.15406$ nm) radiation over the range from 10° to 80° (2θ) with a step size of 0.05°. The crystallite phase was estimated by JCPDS data published by the International Center for Diffraction Data. The average size of the cobalt crystallites was estimated from X-ray diffraction line broadening, using Scherrer's equation, from the most intense Co_3O_4 peak at $2\theta = 36.9^\circ$. The mean Co pellet size d_x in the reduced catalyst was then obtained from the corresponding Co_3O_4 pellet size by applying the relative molar volume correction $d_x(\text{Co}) = 0.75d_x(\text{Co}_3\text{O}_4)$. Then, the Co^0 metal dispersions were calculated using $D = 96/d(\text{Co}^0)$,^{20–22} assuming a spherical geometry of the metal particles with a uniform site density of 14.6 atoms per nm^2 .

2.2.3. Temperature programmed reduction (TPR). The reduction behaviour of the prepared catalysts was studied by H_2 -TPR by using a TP-5080 multi-purpose automatic adsorption instrument. The sample (50 mg) was initially flushed with high purity argon at 150 °C for 1 h and cooled to 50 °C; then, the gas was changed to a H_2/N_2 mixture (5 vol%) and the temperature was increased to 960 °C at a heating rate of 10 °C min^{-1} . The gas flow rate through the reactor was 30 mL min^{-1} . The extent of Co reduction was then calculated from the amount of H_2 consumed during the *in situ* reduction treatment at 400 °C using the reduction of CuO as a ref. 23.

2.2.4. Hg intrusion. The Hg intrusion isotherms and PSDs of the pores larger than 50 nm were measured using a Micro-Active AutoPore Iv 9510 analyzer.

2.2.5. Transmission electron microscopy and scanning electron microscopy measurements. The morphologies of the samples were observed by transmission electron microscopy (TEM) characterization performed on a JEOL:JEM 2010FEF microscope operated at 200 kV. The samples were crushed in an agate mortar and dispersed in ethanol under ultrasonic vibration for 10 minutes. A drop of this suspension was placed onto a holey carbon film on a copper grid (200 mesh). The average Co_3O_4 size was determined by measuring more than 100 particles from several imaged areas. The mean Co pellet size $d_T(\text{Co})$ was obtained from the Co_3O_4 size using the equation $d_T(\text{Co}) = 0.75d_T(\text{Co}_3\text{O}_4)$.

The morphology of the catalysts was determined using a Hitachi-S-4800 scanning electron microscope (SEM, Hitachi High-Technologies CO, Ltd.) operating at 3.0 to 15.0 kV. The samples were sputter-coated with platinum prior to analysis.

2.2.6. Diffuse reflectance FTIR spectroscopy (DRIFTS). The diffuse reflectance FTIR spectra were recorded with a resolution of 8 cm^{-1} and an accumulation of 200 on a Nicolet Magna 750 infrared spectrometer spectrometer supplied with a MCT

detector. High purity CO (>99.99%) was used as a probe gas. Argon and hydrogen (>99.99%) were used as the flushing gas and the reducing gas, respectively. The catalyst was placed in a Spectra Tech catalytic chamber and reduced *in situ* for 6 h under atmospheric pressure with a stream of hydrogen at 400 °C. Subsequently, the system was cooled to room temperature with a stream of hydrogen. After introduction of carbon monoxide for 30 min, the catalyst surface was purged with argon for 5 min to remove gaseous CO; then, the IR spectra were recorded.

2.3 Fischer–Tropsch synthesis catalytic evaluation

1 g of catalyst was mixed with an equal volume of quartz sand which was inert to the FTS and acted as a good thermal conductor to remove heat; the reaction was then evaluated in a stainless-steel fixed-bed reactor (internal diameter = 1 cm, $l = 40$ cm). After reduction at 400 °C for 6 h and cooling to room temperature in a flow of pure hydrogen at 0.5 MPa, syngas (H_2 – CO – N_2 in a volume ratio of 64/32/4; N_2 was used as the internal standard) was introduced to the reactor, and the pressure was increased to 2 MPa. Wax and liquid products were collected by a hot trap (110 °C) and a cold trap, respectively. The effluent product gases were analyzed on-line using a Carbosieve-packed column with a thermal conductivity detector (TCD) and a Porapack-Q column with a flame ionization detector (FID). Oil and wax were analyzed off-line in a GC-920 chromatograph which was equipped with a 35 m OV-101 capillary column and an FID. To ensure reliability of the data, collection of the results began after an initial reaction of 24 h under reaction conditions with the nitrogen balance, oxygen balance, carbon balance and total mass balance in the range of $100 \pm 5\%$.

3 Results and discussion

3.1 Textures of the samples

The structural and textural properties of the supports and the corresponding catalysts were characterized with N_2 adsorption–desorption isotherms, which are displayed in Fig. 1(a) and (b). The isotherms of the support and catalysts exhibited classical irreversible IV type adsorption behavior, with two distinct H1 hysteresis loops at relative pressures P/P_0 of 0.5 to 0.8 and 0.9 to 1.0. The first condensation step on the isotherm at 0.5 to 0.8 indicated the presence of mesopores. The second condensation steps of the catalysts and the support on the isotherm at $P/P_0 > 0.9$ were steeper than the first steps, and the hysteresis loops were wider. This indicated the existence of uniform pores with larger sizes in these samples.¹⁵ The isotherms of nitrogen adsorption and desorption indicated the supports and the catalysts had hierarchical structures. Fig. 1(b) shows that the pore size distributions of the supports and the catalysts were well defined; the maximum distributions were centered at 4 nm and 36 nm, respectively. The smaller mesopores (4 nm) result from the P 123 template, and the larger mesopores may result from voids between the silica aggregates.

The BET surface areas, pore sizes and pore volume data of the supports and the Co/SiO_2 catalysts are listed in Table 1. The pore

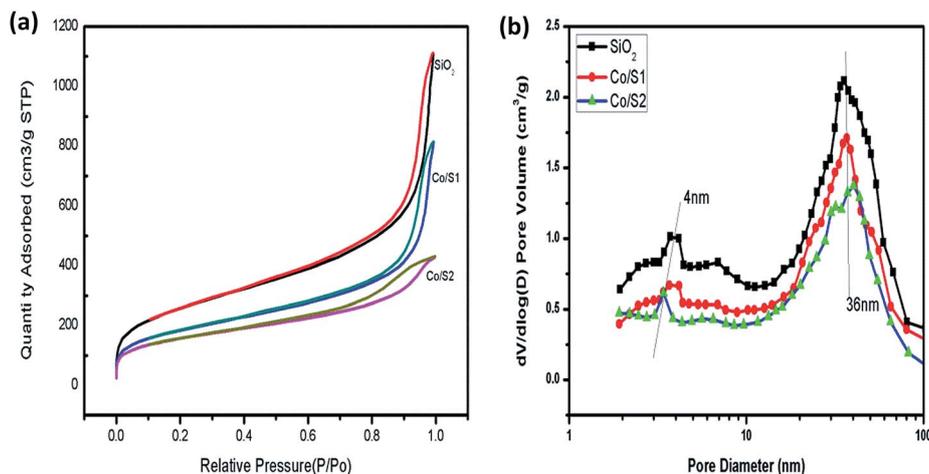

Fig. 1 (a) N_2 physisorption curves of the samples (b) curves of the pore size distribution of the samples.

volume of the hierarchical meso–macroporous SiO_2 support was as large as $1.729\text{ cm}^3\text{ g}^{-1}$; this may be due to the presence of macropores, which can provide channels for rapid molecular transportation. As shown in Table 1, the hierarchical supports and the catalysts all displayed large specific surface areas due to the smaller pores of about 4 nm produced during the sol–gel process, which is beneficial for dispersion of the active components. Compared with the respective supports, the cobalt-loaded catalysts showed lower BET surface areas and pore volumes, which may be due to partial blocking of the pores by cobalt. Catalyst Co/S1 showed a higher BET surface area and pore volume than catalyst Co/S2. This may be due to the severe blocking of the pores by cobalt in catalyst Co/S2, which led to active species aggregation.

3.2 Phase structures of the samples

Fig. 2 shows the wide-angle XRD patterns of the prepared catalysts. For all the catalysts, the diffraction peaks at 2θ of 31.4° , 36.9° , 44.8° , 59.4° , and 65.2° are related to the crystal planes of the spinel Co_3O_4 crystalline phase. The average crystallite sizes of the cobalt oxides, calculated from the Scherrer equation at the highest peak ($2\theta = 36.9^\circ$), are listed in Table 2. Catalyst Co/S2 contained larger crystallites than catalyst Co/S1. These results are related to the pore structures of the supports and will be discussed in detail in the following section.

3.3 Electron microscopy

Electron microscopy studies were carried out to examine the supports. Fig. 3(a) and (b) show SEM images of the hierarchical

SiO_2 support (S1) under lower magnification and under higher magnification, respectively. As shown in Fig. 3(a) and (b), S1 exhibited a honeycomb structure. 3-D ordered macrostructures can be seen in S1. Fig. 3(c) and (d) show SEM images of the SiO_2 support (S2). As shown in Fig. 3(c) and (d), S2 did not have macropores after destructive grinding; instead, it exhibited dispersed pellets. It should be pointed out that a great deal of effort was required to grind S1 into S2 because S1 has excellent mechanical strength.

TEM analysis was conducted to obtain a better understanding of the morphology and distribution of the active species. As shown in Fig. 4, accumulative pores with disordered and worm-like structures could be observed, which are attributed to the larger mesopores (36 nm). Fig. 4(c) and (d) show that in Co/S2, the cobalt aggregation was very severe. However, Fig. 4(a) and (b) show smaller cobalt aggregates in Co/S1, which indicated that Co/S1 had better dispersion. This may indicate the reason why Co/S1 has smaller crystallites. It was very hard to characterize the actual location of the cobalt particles because the mesopores were disordered. We believe some of the cobalt particles are located inside the mesopores; this can be demonstrated by the N_2 adsorption–desorption data, shown in Table 1. Compared with the support, the cobalt catalysts showed lower pore volumes, which may be due to the partial blocking of the pores by cobalt. However, as the mesopores were disordered, some of the cobalt particles may have moved outside the mesopores, on the wall of the macropores. Also, this can be demonstrated by the external surface areas of the supports

Table 1 Structural and textural properties of the supports and corresponding catalysts

Sample	BET surface area ($\text{m}^2\text{ g}^{-1}$)	External surface area ($\text{m}^2\text{ g}^{-1}$)	V_{pore} ($\text{cm}^3\text{ g}^{-1}$)	d_{mesopore} (nm)	$d_{\text{macropore}}$ (nm)

Sample	XRD		TEM		D^b (%)	R^c (%)
	$d_x(\text{Co}_3\text{O}_4)$	$d_x(\text{Co})^a$	$d_T(\text{Co}_3\text{O}_4)$	$d_T(\text{Co})^a$		
Co/S1	12.3	9.2	9.2	6.9	14.5	25.6
Co/S2	17.5	13.1	16	12	8.0	54.3

^a $d_x(\text{Co}) = 0.75d_x(\text{Co}_3\text{O}_4)$, $d_T(\text{Co}) = 0.75d_T(\text{Co}_3\text{O}_4)$. ^b Cobalt dispersion calculated by $D = 96/d_T(\text{Co})$. ^c Reducibility calculated by TPR from 60 °C to 400 °C.

and catalysts. Compared with their respective supports, both cobalt catalysts showed lower external surface areas; this may be because some of the cobalt particles are located outside the mesopores. As mentioned, cobalt particles were located both

inside and outside the mesopores; therefore, the confinement effect of the mesopores was not so obvious. Co/S1 may have smaller cobalt crystallite sizes than Co/S2 because S1 has macropores, which may be beneficial to disperse active components.

3.4 Reduction behavior of the samples

The reduction behaviors and the interactions between the active phase and the support of each catalyst were examined by H_2 -TPR, as shown in Fig. 5. Reduction of Co_3O_4 by hydrogen showed two major regions: first, reduction of Co_3O_4 to CoO (200 °C to 300 °C); then, reduction of CoO to metallic Co (250 °C to 500 °C).^{24–26} The broad peaks between 550 °C and 900 °C were related to the reduction of amorphous Co/silica phase. As shown in Fig. 5, Co/S2 had higher reduction intensity than Co/S1, indicating better reducibility. Co/S1 reveals a broad reduction peak in the range of 600 °C to 900 °C, and Co/S2 reveals a very weak reduction peak at 600 °C; this indicates that more cobalt silicate compound was generated in Co/S1 and also shows that Co/S1 had lower reduction. This is consistent with previous reports that small particles are more difficult to reduce than larger particles.²⁷ However, cobalt silicate was not observed by XRD; this may be because the cobalt silicate was amorphous.

3.5 Hg intrusion

Hg intrusion was conducted to characterize the macropores. As shown in Fig. 6(a), S1 was well defined; the maximum distribution was centered at 1074 nm, which is consistent with the

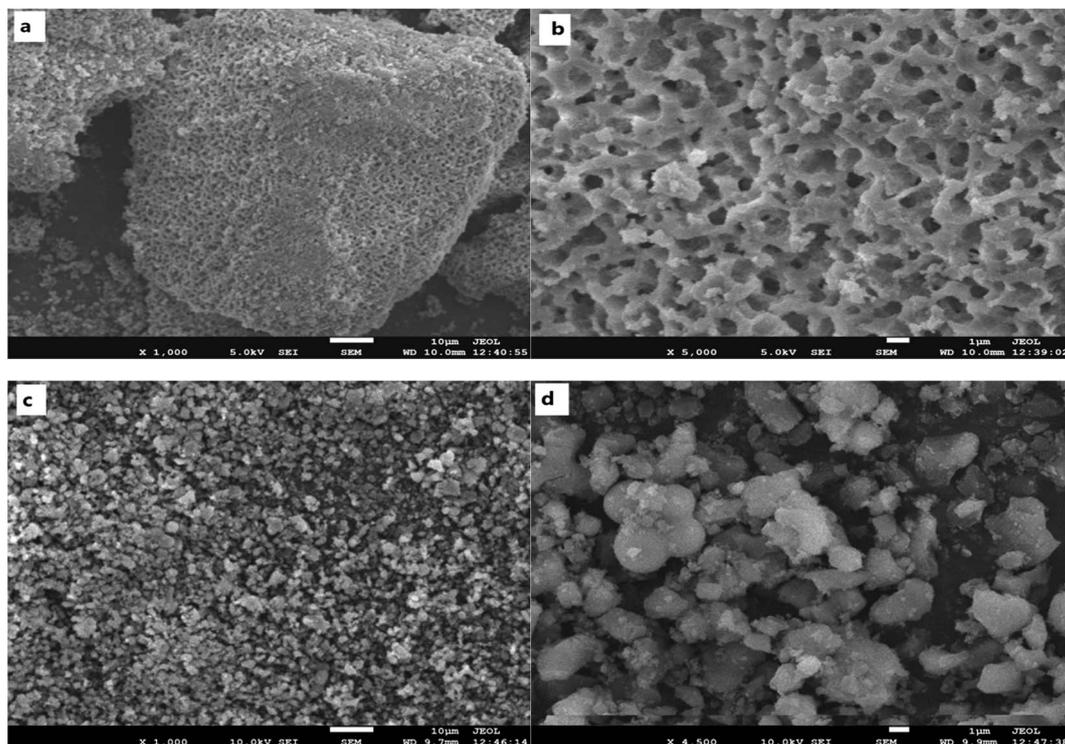

Fig. 3 (a) and (b) SEM images of S1; (c) and (d) SEM images of S2.

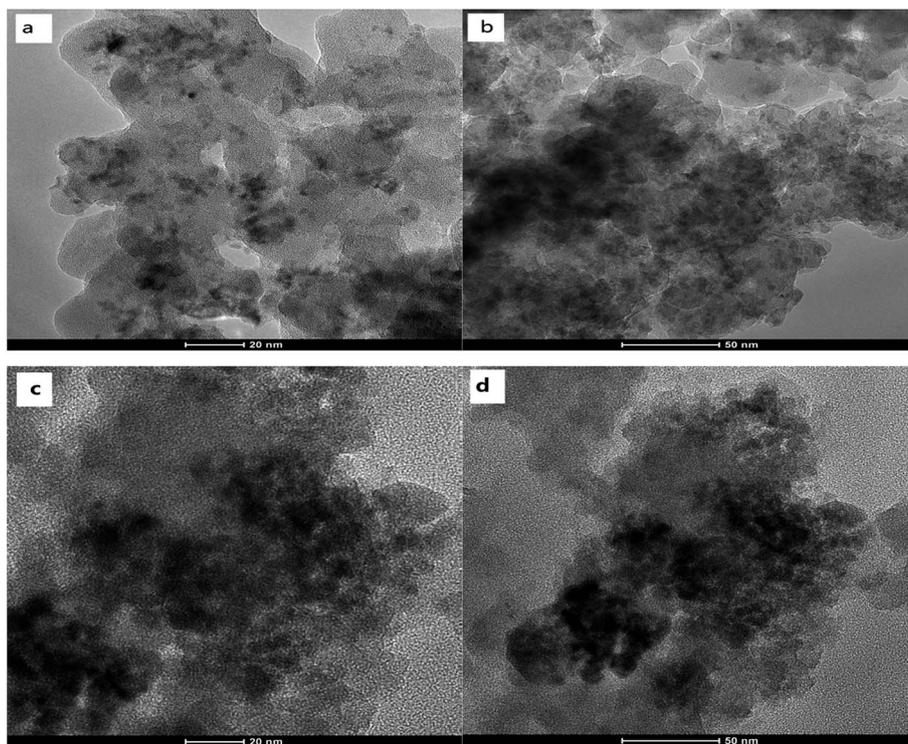

Fig. 4 (a) and (b) TEM Images of Co/S1; (c) and (d), TEM Images of Co/S2.

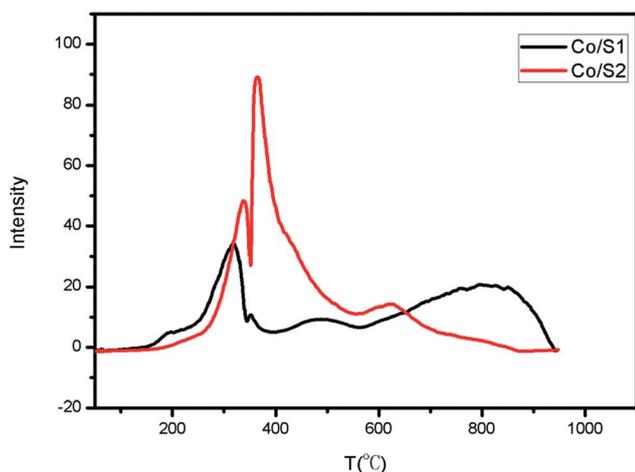

Fig. 5 H_2 -TPR curves of the catalysts.

SEM results. The Hg intrusion and SEM results proved that S1 contains macropores. This indicates that in fact, S1 and Co/S1 have 3-level pore structures, smaller mesopores (about 4 nm), larger mesopores (about 36 nm) and larger macropores (about 1074 nm). Fig. 6(b) shows that there are no macropores in S2. As discussed above, catalyst Co/S2 had larger crystallites than catalyst Co/S1; this may be because the macropores were beneficial to disperse the active components in Co/S1.

3.6 DRIFTS

The diffuse reflectance FTIR spectra of adsorbed CO on the catalysts are shown in Fig. 7. The peaks at 2170 cm^{-1} and 2130

cm^{-1} were assigned to gaseous carbon monoxide. The peak at about 2050 cm^{-1} was assigned to CO adsorbed on cobalt particles in a linear geometry, and the peak at 1935 cm^{-1} is due to bridged CO adsorbed on cobalt metal.²⁸ It has been reported that large cobalt particles provide large, flat metallic surfaces which favor bridge-type adsorption of CO; small particles provide more edges and corners, favoring CO adsorption in a linear geometry.²⁸ Many researchers consider that bridge-type CO is much more active for the FT reaction than linear-type CO due to a weaker C–O bond that can be more easily dissociated to carbon and oxygen; the latter influences the catalytic activity only slightly.²⁹ As shown in Fig. 7, the peak intensities of the linear-type CO adsorption at 2050 cm^{-1} on Co/S1 were much stronger than those of Co/S2; this may be because Co/S1 had smaller cobalt particles and better dispersion. Well-dispersed cobalt with small particle sizes can provide more edges and corner sites for CO to adsorb linearly.²⁹ The peak intensities of bridged CO adsorption at about 1935 cm^{-1} on both the catalysts were very similar, indicating that the two catalysts had similar numbers of active sites available; this suggests the two catalysts had similar activities, although the cobalt particles in Co/S2 were larger than in Co/S1. This may be due to the fact that for Co/S2, the larger particles of cobalt with lower dispersion decreased the number of active sites, resulting in similar bridged CO adsorption to Co/S1. However, the peak at about 1935 cm^{-1} shifted slightly to a lower wave number ($1938 \rightarrow 1935\text{ cm}^{-1}$) from Co/S1 to Co/S2, suggesting that the bridged CO adsorbed on Co/S2 more strongly than on Co/S1.

3.7 Fischer–Tropsch synthesis reaction behaviour

The FTS is a complex reaction which produces a wide range of hydrocarbon products, including paraffin, olefin, and oxygenated compounds.¹⁸ The catalytic results of the FTS reaction are collected in Table 3. It should be noted that all the catalytic data were collected after 24 h under reaction

conditions where a steady state for the formation of the product was obtained.

As we discussed in the introduction, large pellet catalysts exhibit severe internal diffusion limitations; however, small pellet catalysts do not have this problem. Iglesia *et al.*³⁰ explained that the high methane selectivity and low C₅₊ selectivity caused by diffusion-inhibited chain growth probability became more severe if the catalyst pellet size was larger than 360 μm or the structure parameter (χ) increased above $200 \times 10^{16} \text{ m}^{-1}$. The structure parameter (χ) can be estimated as follows:

$$\chi = L^2 \theta \psi / r_p \quad (1)$$

where L is the average radius of the catalyst pellets; θ is the areal density of the active sites; ψ is the void fraction of the catalyst pellets; and r_p is the support pore radius. In the present work, in Co/S1/10–20 and Co/S2/10–20 (pellet sizes about 830 to 1700 μm), internal diffusion limitations played an important role; however, in Co/S1/60–80 and Co/S2/60–80 (pellet sizes about 180 to 250 μm), there were no internal diffusion limitations.

Comparing Co/S1/60–80 with Co/S2/60–80, we found that the two catalysts showed similar CO conversion. It is known that the catalytic activity is affected by the synergy of reducibility and

Table 3 The performance of different catalysts for Fischer–Tropsch synthesis^a

Catalyst	T (°C)	TOF	CO Conv. (%)	Product selectivity [%]

^a Reaction conditions: H₂/CO = 2, P = 2 Mpa, GHSV = 2.4 L (g⁻¹ h⁻¹), TOS = 24 h.

cobalt dispersion.¹⁴ Co/S2/60–80 was more readily reduced; however, it did not exhibit higher CO conversion, probably because aggregation of the particles seriously decreased the cobalt dispersion, which was proportional to the number of surface active sites and exposed metal atoms. For Co/S1/60–80, the decreased catalytic activity, which results from the lower reduction degree, may be offset by the enhanced cobalt dispersion. The DRIFTS results showed that the peak intensities of bridged CO adsorption on Co/S1 and Co/S2 were similar, which is in agreement with the FT results. Co/S1/60–80 showed higher methane selectivity and lower C₅₊ selectivity than Co/S2/60–80; this may be because Co/S1/60–80 ($d_{\text{Co}} = 6.9$ nm) had a smaller cobalt crystal size than Co/S2/60–80 ($d_{\text{Co}} = 12$ nm). For smaller (<10 nm) Co particles, a decrease in FT performance has been reported.³¹ Using cobalt on carbon nanofiber (CNF) catalysts, tested at both 1 bar and 35 bar, Bezemer *et al.*³¹ showed that methane selectivity increased with increasing cobalt crystal size; the methane selectivity become constant when the cobalt particles were larger than 6 nm (1 bar) and 8 nm (35 bar). Also, the larger particles showed higher C₅₊ selectivity at the same temperature. Although inert supports are very different from porous oxide supports, the same trends were reported by Øyvind Borg and co-workers,³² who used cobalt catalysts supported on Al₂O₃ (γ -Al₂O₃ and α -Al₂O₃). Several suppositions have been used to explain higher methane selectivity in FT synthesis over small Co particles. First, the high methane selectivity was attributed to sites of weak carbon monoxide adsorption.³³ The DRIFTS results showed that the bridged CO adsorbed on Co/S2 shifted slightly to a lower wave number (1938 \rightarrow 1935 cm⁻¹) compared with Co/S1, indicating that the bridged CO adsorbed on Co/S2 more strongly than on Co/S1. Therefore, the higher methane selectivity of the small Co particles in Co/S1/60–80 obtained with the FT conditions may result from the weak adsorption of Co on the active sites. Second, Breejen *et al.*³⁴ attributed the higher methane selectivity of small Co particles to their higher hydrogen coverage by Steady-State Isotopic Transient Kinetic Analysis (SSITKA) using cobalt on carbon nanofiber (CNF). Third, Reuel and Bartholomew³⁵ attributed the higher methane selectivity to the presence of stable unreduced oxide phases capable of catalyzing the water–gas shift reaction ($\text{CO} + \text{H}_2\text{O} \rightarrow \text{CO}_2 + \text{H}_2$), thereby increasing the H₂/CO ratio at the catalyst surface. Our data do not agree with this interpretation of higher methane selectivity because carbon dioxide was not detected among the reaction products. As discussed above, the higher methane selectivity for smaller cobalt particles of Co/S1/60–80 may be due to the higher coverage of hydrogen and the weak adsorption of CO on the active sites. The TOF was also calculated, as shown in Table 3. Comparing Co/S1/60–80 with Co/S2/60–80, we found that the TOF of Co/S2/60–80 was higher than that of Co/S1/60–80, although their CO conversion was very similar. The difference in TOF may be due to the influence of the cobalt crystalline size. Bezemer *et al.*³¹ observed that the TOF gradually increased with cobalt crystalline size in the range of 2.6 to 8 nm and then was constant for larger sizes (8 to 20 nm). Park *et al.*³⁶ also found that the TOF increased sharply with Co particle size from 4.8 to 9.3 nm and then decreased slightly as the cobalt crystalline size further increased. Our group also

obtained the same results using core–shell-structured catalysts; however, the critical size was about 8.7 nm.¹³ Based on the above discussion, we can attribute the higher TOF of Co/S2/60–80 to its larger cobalt crystalline size (12 nm) compared to that of Co/S1/60–80 (6.9 nm).

Comparing Co/S1/10–20 with Co/S2/10–20, we found that Co/S1/10–20 had higher CO conversion, lower methane selectivity and higher C₅₊ selectivity than Co/S2/10–20. In addition, we found that the TOF of Co/S1/10–20 was higher than that of Co/S2/10–20, although Co/S2 had a larger cobalt crystalline size than Co/S1. Although the cobalt dispersion, crystal size and reducibility had important effects on FT performance, we prefer to attribute the difference to the existence of macropores in Co/S1/10–20. The effects of internal diffusion limitation existed in both catalysts. However, Co/S1/10–20 contains macropores. The existence of these numerous macropores in Co/S1/10–20 greatly diminished the influence of the internal diffusion limitations due to the large catalyst pellet size, which affects both the catalytic activity and hydrocarbon selectivity. Therefore, this demonstrates that the macropores played an important role in reducing the effects of internal diffusion limitations.

As shown in Table 3, at the same temperature, Co/S1/10–20 and Co/S1/60–80 displayed very similar product selectivities; the selectivity of methane differed by 3.14% and the C₅₊ selectivity differed by 2.80%. It was found that the C₅₊ selectivity of Co/S1/10–20 was slightly decreased and the methane selectivity of Co/S1/10–20 was slightly increased compared with those of Co/S1/60–80. This was mainly attributed to the slight diffusion restrictions of the reactants and products, which considerably affected the variation in the hydrocarbon product selectivity in Co/S1/10–20. However, because of the existence of macropores in Co/S1/10–20, the internal diffusion limitations were not as severe. The ASF distributions and α -chain lengthening probabilities were also very similar for Co/S1/10–20 and Co/S1/60–80, as shown in Fig. 8. However, Co/S2/10–20 and Co/S2/60–80 showed very different FT performances; the selectivity for

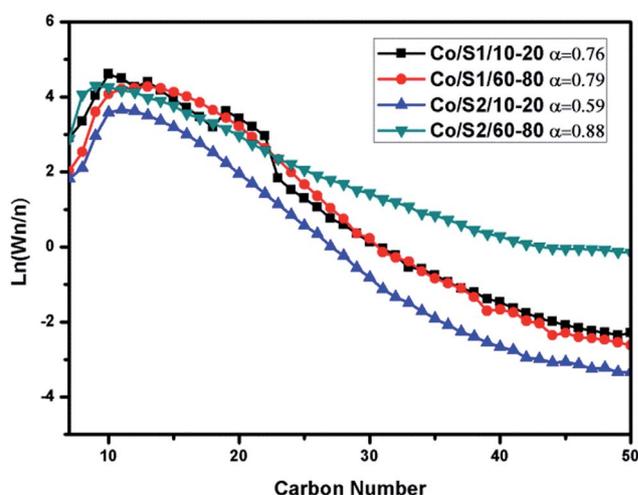

Fig. 8 ASF distributions of the catalysts and α -chain lengthening probabilities. Conditions: $T = 240$ °C, $\text{H}_2/\text{CO} = 2$, $P = 2$ Mpa, GHSV = 2.4 L ($\text{g}^{-1} \text{h}^{-1}$), TOS = 24 h.

methane differed by 17.44%, and the C₅₊ selectivity differed by 17.27%. Co/S2/10–20 showed higher methane selectivity, lower CO conversion and lower C₅₊ selectivity than Co/S2/60–80. In addition, the α value of Co/S2/60–80 (0.88) was much higher than that of Co/S2/10–20, and the ASF distributions were greatly different. As there were serious internal diffusion limitations in Co/S2/10–20, which were more pronounced for CO than for H₂ due to different diffusion coefficients, the concentration of CO decreased more, leading to a high H₂/CO ratio on the surface of the active sites. Thus, for Co/S2/10–20, the selectivity of methane was very high and the C₅₊ selectivity was low. However, in Co/S2/60–80, the internal diffusion limitations were not so obvious due to the small pellet size, which contributed to better FT performance. These phenomena can be described by the structural parameters, as stated in eqn (1).³⁰ Because the L value is the exponential term, the effect of this value on the structural parameters is greater than on the other parameters.¹⁸ Based on the above discussion, we found that: (1) for FT synthesis, large pellet catalysts showed poor results compared to small pellet catalysts because of the existence of serious internal diffusion limitations; (2) in large pellet catalysts, macropores can help reduce the internal diffusion limitations.

4 Conclusions

In the present work, hierarchical meso–macroporous silica (S1) and bimodal mesoporous silica (S2) were synthesized by a sol–gel process and used as cobalt supports for Fischer–Tropsch synthesis (FTS). Co/S1 had a 3-level pore structure, and Co/S2 had a bimodal mesoporous structure. It was found that the macroporosities of the catalysts had significant effects on the physico-chemical properties of the cobalt catalysts and also played important roles in the FTS reaction. It was found that when macropores were present, the large pellet catalyst displayed very similar FT performance to the small pellet catalyst. However, in the absence of macropores, the large pellet catalyst displayed much higher methane selectivity than the small pellet catalyst, while CO conversion and C₅₊ selectivity displayed the opposite trends. Also, the large pellet catalyst with macropores displayed much better FT performance than the large pellet catalyst without macropores. This evidence clearly confirmed the positive effects of abundant macropores on the rapid transport of reactants and products.
