Design and synthesis of dual probes for detection of metal ions by LALDI MS and fluorescence: application in Zn(II) imaging in cells†

Arundhoti Mandal,a Asim Maitya,b Swarnendu Bag,b Prabuddha Bhattacharya,a Amit K. Dasb and Amit Basak*a

A Label-Assisted Laser Desorption/Ionization (LALDI) technique has recently been applied to the detection of metal ions through a time of flight (TOF) mass spectrometric measurement. In this paper, we report the synthesis of two terpyridine based ligands L1 and L2 containing a pyrene moiety. The presence of the latter helped the ligand metal complex to desorb from the surface and ionize upon laser irradiation and finally show up in the TOF MS. Both ligands were able to detect Zn2+, Ni2+ and Co2+ ions while Cu2+, Fe2+ and Mg2+ remained LDI silent. Complexation with the ligands also caused a red fluorescence only with Zn2+ ions that allowed Zn2+ imaging in cells. Thus the pyrene moiety acts as a dual probe for metal ion detection exploiting both LALDI MS and fluorescence techniques.

Introduction

Metal ions play a crucial role in normal cellular function.1 In biological systems, they can function in a number of different ways. They act as cofactors for many critical enzymatic reactions.2 Some metals operate as structural elements3 and maintain charge and osmotic balance.4 Transition metal ions such as zinc(ii), function as structural elements in superoxide dismutase5 and in zinc finger proteins.6 There are also a number of reports on activation of chemical reactivity of small molecules upon metal ion chelation.7 For example, acyclic enediyynes with terminal ligands undergo Bergman cyclization8 at a lower temperature for the metal complexed system as compared to the uncomplexed one. Interestingly, presence of metal ions in excess or less in biological systems can have adverse effects. Every essential element follows a dose–response curve. At very low dosages, the organism struggles to survive, whereas in depletions caused by toxic concentrations plateau in the optimum dosage region, higher organism exists with sub-optimal function. Beyond the becoming lethal.9

In recent years, our group has demonstrated the use of LALDI MS technique involving an oxine carboxylic acid–pyrene conjugate ligand for selective detection of metal ions like Zn$^{2+}$. However, although the detection was easily discernible, the quality of the spectra was less than satisfactory. This is because of low sensitivity and low absorption of the ligand at laser wavelength of 337 nm as well as appearance of extra peaks originating from the ligand. With the aim of improving the spectra particularly at the low level of detection and removal of extraneous peaks, we have designed the terpyridine based ligands $L_1$ and $L_2$ (Fig. 2) attached with a pyrene moiety through ester linkage or through conjugation. Terpyridine is a tridentate ligand that binds metals at three meridional sites and it forms complexes with transition metal ions. The ligand has been well exploited for complexation with various metal ions. Recently, Ghosh et al. have reported in an interesting paper the design and synthesis of an alkynyl terpyridine which has been shown to form octahedral complexes with metal ions like Fe$^{2+}$, Zn$^{2+}$, Cd$^{2+}$, Ru$^{2+}$ and Pb$^{2+}$. Another recent work has been reported by Patra et al. on terpyridine based sensor for detection of Cd$^{2+}$. However, to our knowledge, there is no report of any pyrene based terpyridine ligand which has been used to serve the dual purpose of detection of metal ions by both LALDI MS as well as by fluorescence sensing. Pyrene moiety is known for its ability to act as an excellent LDI tag, due to its chemical inertness, ability to form radical cations and most importantly, very high molar extinction coefficient in the range 335–360 nm which allowed it to absorb laser radiation and subsequent desorption-cum-ionization. The pyrene–terpyridine conjugate should form chelate complex with analyte metal ions and the entire complex upon laser irradiation is expected to undergo desorption-cum-ionization and should be detectable by LDI-MS. The working principle is shown in the Fig. 3. In addition, the pyrene moiety was also expected to serve as the fluorophore changing its emission spectra upon complexation. In this paper, we describe the synthesis of ligands $L_1$ and $L_2$ and report their ability to detect metal ions by using a combination of LALDI MS and fluorescence.

**Results and discussion**

Both the ligands were synthesized starting from a common intermediate, namely 4′-(4-bromomethylphenyl)terpyridine 2 (Fig. 4). For this, the tolyl terpyridine 1 was first synthesized following the literature procedure reported by Zecher and Kröhnke. This synthetic protocol involves condensation reaction between 2-acetyl pyridine and 4-methylbenzaldehyde in presence of ammonia and NaOH to yield intermediate 1. Allylic bromination was performed using NBS and AIBN on 1 to obtain

compound 2. The desired ligand \( L_1 \) was formed when 2 was reacted with sodium salt of pyrene butyric acid 3. The ligand \( L_2 \) was synthesized via Wittig reaction between the Wittig salt 4 and pyrene aldehyde in presence of \( n \)-BuLi. The structures of \( L_1 \) and \( L_2 \) have also been confirmed by \( ^1H, ^13C \) NMR (included in ESI†).

With the ligands in hand, we first checked whether these are LDI active. For this, an aliquot of 1 \( \mu \)L of the prepared ligand solution of 1 \( \mu \)M in chloroform was spotted in the LDI plate and the mass spectrum (TOF-MS) was recorded. Due to high molar extinction coefficient of pyrene, ligand \( L_1 \) showed a strong \([\text{MH}]^+\) peak at \( m/z \) 610 (Fig. 5) while ligand \( L_2 \) showed the peak at \( m/z \) 536 (Fig. 6). Expectedly, because of greater conjugation, the ligand \( L_2 \) absorbs the laser to a greater extent and hence the corresponding LALDI spectrum of ligand \( L_2 \) appeared to be clearer than ligand \( L_1 \).

For screening the metal ion complexation, the concentration of probe (\( L_1 \) or \( L_2 \)) was maintained at 0.1 \( \mu \)M and that of metal perchlorate salts at 1 \( \mu \)M in acetonitrile. The reaction mixtures were incubated for 2 h at 40 °C. An aliquot of 1 \( \mu \)L from the reaction mixture were taken from each reaction mixture and analyzed (TOF-MS) in positive ion mode. The captured complexes of \( \text{Zn}^{2+}, \text{Co}^{2+}, \text{Ni}^{2+} \) were LDI active with typical isotopic distributions while \( \text{Fe}^{2+}, \text{Cu}^{2+} \) remained LDI silent. The summarized results of the screening process are given below in Table 1. The spectrum for \( \text{Zn}^{2+} \) with \( L_1 \) and \( L_2 \) are shown in Fig. 7 and 8 respectively.

Regarding sensitivity of detection for \( \text{Zn}^{2+} \) using the present protocol, we could determine \( \text{Zn}^{2+} \) at an impressive level of 0.025 \( \mu \)M (Fig. 9). The isotopic distribution also followed the theoretically predicted one (Fig. 10).

The LALDI mass spectrum of ligand \( L_2 \) and Co(ClO4)2 was compared with the spectra obtained via conventional MALDI technique (Fig. 11). It clearly showed the advantage of LALDI over MALDI for small molecule detection. Moreover our synthesized probe can detect metal ion in presence of other organic impurities, ubiquitous in biological fluids like glucose, amino acid, \( \alpha \)-ketoglutaric acid and tartaric acid, which cannot be accomplished by any other LDI techniques (Fig. 12). Even it can detect the presence of all three metal ions like Co\({}^{2+}, \text{Zn}^{2+}\) and Ni\({}^{2+}\) in a mixture (Fig. 13).

We have also recorded the fluorescence and UV-spectral changes upon complexation (Fig. 14 and 15). The UV and fluorescence experiments were carried out in acetonitrile medium at 10 \( ^{-5} \) M concentration of ligand solution upon addition of incremental amount of metal perchlorate (in order of 200 \( \mu \)M). The UV-VIS spectrum of the ligand \( L_1 \) exhibits maxima at 242 nm and 275 nm. For \( \text{Zn}^{2+}, \text{Ni}^{2+} \) and \( \text{Co}^{2+} \), upon gradual increase of

metal ion concentration, a new peak (284 nm for Co²⁺ and 285 nm for Zn²⁺ and Ni²⁺) was observed. No change was observed for Fe²⁺, Cu²⁺, Mg²⁺. Ligand L₂ exhibited maxima at 384 nm. For Zn²⁺, Ni²⁺ and Co²⁺ shift of ligand peak was observed i.e., 384 nm to 407 nm for Zn²⁺, to 403 nm for Co²⁺ and to 405 nm for Ni²⁺. No change was observed for Fe²⁺, Cu²⁺, Mg²⁺. This also indicates the greater chelating ability of terpyridine moiety towards Zn²⁺, Ni²⁺ and Co²⁺.

Fluorescence data for ligand L₂ were recorded at excitation wavelength of 360 nm. The free ligand showed emission maxima at 487 nm. Upon gradual increase of metal ion concentration, quenching of fluorescence was observed for all metal ions. Many transition metals are known to be fluorescence quenchers, and they can quench fluorescence through energy transfer or electron transfer mechanisms. The phenomenon of quenching in case of Zn²⁺, Ni²⁺ and Co²⁺ was very high compared to Fe²⁺, Mg²⁺, Cu²⁺. The greater extent of quenching in case of Zn²⁺, Ni²⁺ and Co²⁺ suggested formation of complexes causing easier energy transfer. This is also supported by LALDI-MS and UV-VIS studies. In case of Zn²⁺, apart from quenching of fluorescence, a new peak was observed at 620 nm with increasing Zn²⁺ concentration (Fig. 15b and c), it also showed a vivid colour change from yellow to red under UV lamp (Fig. 16). The new peak may be due to ligand to metal ion intramolecular charge transfer (ICT). The synthesized ligand L₁ had very low fluorescent power, thus the experiment was carried out using a greater slit width of the fluorimeter. The fluorescence spectrum (Fig. 15a) of L₁ was recorded at an excitation wavelength of 280 nm and it showed emission maxima at 378 nm. Upon gradual addition of Zn²⁺ concentration, the nature of the curve completely changed indicating strong complexation. However, unlike L₂, no new band in the visible region was observed. Small changes were also noticed for Ni²⁺ and Co²⁺, but no change was observed for Fe²⁺, Mg²⁺, Cu²⁺.

Encouraged by the outcome of fluorescence study we proceeded to the *in vitro* cell imagine for the staining of the zinc ion by the ligand L2. In this experiment we targeted HaCaT cell line for imaging studies. HaCaT is a spontaneously transformed aneuploid immortal keratinocyte cell line from adult human skin, widely used in scientific research.11

Considering the merits required for cell-imaging study, our object was to locate zinc ion in living cell by employing the higher fluorescent property of the ligand L2 and its greater affinity for zinc ion at biologically relevant environment.

As predicted beforehand, the ligand L2 can selectively sense zinc ions in cell. The control cells and the cells only treated with Zn(ClO4)2 showed no red (Fig. 17A and B) but blue fluorescence was observed due to staining of the nucleus by DAPI. The cells treated with only ligand L2 showing the red fluorescence having less intensity (Fig. 17C) but the cells treated with both zinc salt and ligand showed more intense red fluorescence in high intensity (Fig. 17D).

When HaCaT cell were incubated with only ligand L2 very faint fluorescence expression was observed due to the zinc...
SoD2 in mitochondria), but the zinc treated cell showed strong fluorescence microscopy-200× magnification of cells treated as follows: (A) control (B) cell treated with Zn(ClO4)2 (C) cell treated with ligand L2 (D) cell treated with Zn(ClO4)2 + ligand L2 [red color indicates the fluorescence dye/ligand. Yellow arrow indicates the staining by the red fluorescence. Blue color indicates nucleus of the cell stained by DAPI (4',6-diamidino-2-phenylindole)].

containing enzymes like metalloproteases, super oxide dismutase which reside in extracellular region (SoD1 in cytoplasm, SoD2 in mitochondria), but the zinc treated cell showed strong red fluorescent signal after incubating it with ligand indicating a subcellular distribution of zinc ion. It suggests that zinc mapping is possible for the synthesized probe L2.

Conclusion

In conclusion, we have successfully synthesized pyrene–terpyridine ligands for detection of their metal ion complexation property. One of the ligand also acted as a new fluorescent probe highly selective for zinc ion in presence of other metal ions in the biologically relevant range. Zinc ion imaging was demonstrated using ligand L2 in HaCaT cell by observing interaction of Zn2+ with ligand L2. Ligand L2 showed strong red fluorescence for Zn2+ accumulated in the mitochondrial part of HaCaT cell.

DST is acknowledged for an SERC grant (SB/S1/OC-94/2013) and for the JC Bose Fellowship to AB which supported this research. AM is grateful to IIT Kharagpur for a senior research fellowship and PB is grateful to CSIR, Government of India, for a research fellowship.

References

An alternate structure of Zn(II) complex could be thought of where the two ligands H₂O and OH are replaced by Cl. However, the absence of isotopic peaks due to ³⁵Cl and ³⁷Cl made us to believe that it is indeed OH and H₂O acting as the ligands. We have not seen the formation of dimers as was reported by Ghosh, et al. during incubation of ligand with the metal perchlorates which may be due to the bulky pyrene ring adding some steric compression in the dimeric complex. We thank the referee for drawing our attention to this aspect. The spectrum showed in Fig. 12 is that of cobalt(n) complex with I₂. The spectrum is not that bad even in presence of matrix as the polyaromatic absorbing the laser is already present. But if we use acetylacetone as the ligand, the spectrum of the cobalt complex in presence of matrix showed a small peak for Co(acac)₃ complex. This showed the advantage of using the polyaromatic label. The new spectrum of Co(acac)₃ in presence of matrix is included in ESI.†
