1. Introduction

Recently, oxide materials with giant dielectric permittivity have found an important role in microelectronic devices and high-density storage applications such as capacitors and memory devices.\(^1\)\(^-\)\(^4\) One of the most interesting giant dielectric materials is CaCu\(_3\)Ti\(_4\)O\(_{12}\) (CCTO) ceramics. CCTO exhibited giant dielectric permittivity (\(\varepsilon' > 10^4\) at 1 kHz) over a wide temperature range from 100 to 600 K.\(^3\) The \(\varepsilon'\) value of CCTO ceramics was also weakly dependent on frequency in the radio frequency range. Unfortunately, the loss tangent (\(\tan \delta\)) of CCTO was still too large for practical applications in ceramic capacitors.\(^5\)\^-\(^9\)

Improved giant dielectric properties of CaCu\(_3\)Ti\(_4\)O\(_{12}\) via simultaneously tuning the electrical properties of grains and grain boundaries by F\(^-\) substitution

Jutapol Jumapatam,\(^a\) Bundit Putsaeng,\(^b\) Narong Chanlek,\(^c\) Pinit Kidkhunthod,\(^c\) Prasit Thongbai,\(^*\)\(^d\) Santi Maensiri\(^e\) and Prinya Chindaprasirt\(^f\)

A novel concept to simultaneously modify the electric responses of the grain and grain boundaries of CaCu\(_3\)Ti\(_4\)O\(_{12}\) ceramics was proposed, involving doping with F\(^-\) anions to improve the giant dielectric properties. The grain growth rate of CaCu\(_3\)Ti\(_4\)O\(_{12}\) ceramics was enhanced by doping with F\(^-\) anions, which were found to be homogeneously dispersed in the microstructure. Substitution of F\(^-\) anions can cause an increase in the resistance of the insulating grain boundary and a decrease in the grain resistance. The former originated from the ability of the F\(^-\) dopant to enhance the Schottky barrier height at the grain boundaries, leading to a great decrease in the dielectric loss tangent by a factor of 5 (\(\tan \delta < 0.1\)). The latter was primarily attributed to the increase in Ti\(^{3+}\) and Cu\(^{+}\) concentrations due to charge compensation, resulting in a significantly enhanced intensity of space charge polarization at the grain boundaries. This is the primary cause of the increase in dielectric permittivity from \(\approx 10^4\) to \(\approx 10^5\).

The giant dielectric and electrical properties were well described by the Maxwell–Wagner polarization relaxation based on the internal barrier layer capacitor model of Schottky barriers at the grain boundaries.

Even now, the origin of giant dielectric response is still open to scientific debate. Most research groups believe that the extrinsic origin of the internal barrier layer capacitance (IBLC) mechanism at grain boundaries (GBs) is the primary cause of the giant dielectric response in CCTO ceramics.\(^12,14,20\)\^-\(^21\)

According to the IBLC mechanism, the giant dielectric response in a polycrystalline ceramic is driven by its electrically heterogeneous microstructure. This special microstructure can be fabricated using a one-step processing method that forms insulating GBs sandwiched between n-type semiconducting grains. The electrical responses of the grain and GB can have a remarkable influence on the dielectric properties of CCTO ceramics.\(^12,14,15,22\)

Moreover, due to the existence of this special microstructure, CCTO ceramics can also exhibit the non-ohmic properties (or nonlinear current density–electric field, \(J–E\)).\(^24,25\)

This special behavior is believed to originate from the existence of an intrinsic potential barrier (i.e., Schottky barrier) at GBs.\(^26\)

The presence of an electrostatic barrier at the GBs of CCTO ceramic was clearly confirmed using Kervin probe force microscopy.\(^24\)

To improve the dielectric properties of CCTO ceramics, most investigations have focused on substitution of one of several doping cations into CCTO ceramics to tune the electrical properties of the grains and GBs. It has been widely demonstrated that enhancement of the GB resistance (\(R_{\text{gb}}\)) can reduce the low-frequency \(\tan \delta\) value.\(^15,23,26\)

According to the space
charge polarization theory (or interfacial polarization), an increase in mobile charges inside the semiconducting grains can lead to the possibility of accumulating free charges at the interface of insulating layers. This gives rise to a stronger intensity of the polarization at internal insulating interfaces, leading to an increase in $\varepsilon'$. The giant dielectric properties of CCTO ceramics were first reported by Subramanian et al. There are further several reports of dopant cations substituted into CCTO ceramic such as Sr$^{2+}$, La$^{3+}$, Ni$^{2+}$, Mg$^{2+}$, Cu$^{2+}$, Ga$^{3+}$, Zn$^{2+}$, Sn$^{4+}$, Ni$^{5+}$, Ta$^{5+}$ (ref. 12) and W$^{6+}$ (ref. 13). Substitution of many cations into Ca$^{2+}$, Cu$^{2+}$ and Ti$^{4+}$ sites in CCTO ceramics have significant effects on the values of their $\varepsilon'$, $\tan\delta$, electrical conductivity of the GBs ($\sigma_{gb}$) and activation energies at the GBs ($E_{gb}$) and inside the grain ($E_g$). Usually, all of these dopants can be successfully used to improve a particular dielectric property (e.g., to reduce $\tan\delta$ or enhance $\varepsilon'$), while they simultaneously worsen other important dielectric properties of these materials. For example, substitution of higher cations into Ti$^{4+}$ sites would increase free charges inside the semiconducting grains due to the excess electron of a dopant (e.g., Nb$^{5+}$ or Ta$^{5+}$). This can cause an increase in $\varepsilon'$, which resulted from the enhanced space charges at the insulating interfaces. Unfortunately, it also causes a large decrease in $R_{gb}$, leading to a signiﬁcant increase in a low-frequency $\tan\delta$. Alternatively, doping CCTO with Mg$^{2+}$ into Cu$^{2+}$-sites can decrease $\tan\delta$ However, the $\varepsilon'$ value of Mg-doped CCTO was also decreased due to the decrease in free charges inside the grains, considering by the increase in $R_{gb}$.

It is expected that doping CCTO with an anion can increase free charges inside the grains due to charge compensation. Substitution of F$^-$ into O$^{2-}$ sites is electrically compensated by reduction of valance state of Ti$^{4+}$ to Ti$^{3+}$ and Cu$^{2+}$ to Cu$^+$. It was clearly demonstrated that filling oxygen vacancies at the GBs can strongly increase $R_{gb}$ value by annealing in an O$_2$ atmosphere. Alternatively, $R_{gb}$ can be reduced by creating the oxygen vacancies at the grain boundaries via annealing in a N$_2$ atmosphere. Thus, it is also expected that substitution of F$^-$ anions may have no effect on the insulating properties of the GBs because oxygen vacancies along the GBs are usually filled during cooling step of the sintering process. This also helps retain the insulating nature of the GBs. To the best of our knowledge, there have been few reports of an anion dopant being substituted into CCTO ceramics. The effects of anion dopant on the microstructure and electrical properties of the grain and GB have never been reported.

In this work, a new strategy to improve the dielectric properties of CCTO ceramics was used by doping with F$^-$ anions to modify the electrical responses of the grains and GBs. The effects of F$^-$ anions on the microstructural evolution and associated dielectric properties were studied and discussed. As expected, doping CCTO ceramics with F$^-$ anions at O$^{2-}$ sites resulted in improved dielectric properties via a large enhancement of $\varepsilon'$ and significant decrease in $\tan\delta$.

2. Experimental procedure

CaCu$_3$Ti$_4$O$_{12-\delta}$F$_x$ ceramics, where $x = 0, 0.05, 0.1$, and $0.2$ (referred to as the CCTO, F05, F10 and F20 samples, respectively), were prepared using a solid state reaction method. The starting materials used were CaCO$_3$ (Aldrich, $\geq$99.0% purity), CuO (Merck, 99.9% purity), CuF$_2$ (Sigma-Aldrich, 99.9% purity), and TiO$_2$ (Sigma-Aldrich, 99.9% purity). First, a stoichiometric mixture of the starting materials for each composition was mixed by ball milling using zirconia (ZrO$_2$) media in ethanol for 12 h. Second, the mixed slurries were dried and calcined at 900 °C for 15 h. Then, the calcined powders were ground and pressed into pellets with 9.5 mm in diameter and 1-2 mm in thickness by a uniaxial compression at 200 MPa. Finally, these pellets were sintered in air at 1075 °C for 3 h.

The phase composition and crystal structure were characterized using X-ray diffraction (XRD; PANalytical EMPYREAN). Rietveld quantitative phase analysis was done using the XPert High Score Plus v3.0e software package by PANalytical. The as-sintered ceramics were carefully polished to obtain smooth surfaces. The grain and GB structure of the polished-samples was formed by thermally etching at 1050 °C for 1 h. Surface morphologies of sintered ceramics were revealed using scanning electron microscopy (SEM; SEC, SNE-4500M). X-ray Absorption Near Edge Structure (XANES) spectra were collected at the SUT-NANOTEC-SLRI XAS beamline (BL5.2) (using an electron energy of 1.2 GeV, a bending magnet, beam current of 80–150 mA, and 1.1 to 1.7 × 10$^{13}$ photons per s) at the Synchrotron Light Research Institute (SLRI), Nakhon Ratchasima, Thailand. Details of this characterization technique have been published.[26] The normalized XANES data were processed and analyzed after background subtraction in the pre-edge and post-edge region using ATHENA software that is included in the IFEFFIT package.[27] The chemical states of Cu and Ti were analyzed using X-ray photoelectron spectroscopy (XPS), PHI5000 VersaProbe II, ULVAC-PHI, Japan) at the SUT-NANOTEC-SLRI Joint Research Facility, Synchrotron Light Research Institute (SLRI), Thailand. The XPS spectra were fitted using PHI MultiPak XPS software with a combination of Gaussian–Lorentzian lines.

Before electrical measurements, both surfaces of the sintered ceramics were polished until smooth, washed, and dried at 150 °C overnight. The polished samples were coated by sputtering Au on their surfaces for 8 min at 25 mA using a Poloron SC500 sputter coating unit. The dielectric properties were measured over the temperature range of −70 to 220 °C using a KEYSIGHT E4990A Impedance Analyzer in the frequency range of 10$^2$ to 10$^7$ Hz with an oscillation voltage of 0.5 V. Each measurement temperature was kept constant with a precision of ±0.1 °C. Nonlinear $J$-$E$ properties at room temperature (RT) were determined using a high voltage measurement unit (Keithley Model 247). The breakdown
electric field \( (E_b) \) was achieved at \( J = 1 \text{ mA cm}^{-2} \). The nonlinear coefficient \( (\alpha) \) was calculated using the following formula:

\[
\alpha = \frac{\log(J_2/J_1)}{\log(E_2/E_1)}
\]

where \( E_1 \) and \( E_2 \) are the applied electric fields, at \( J_1 = 1 \) and \( J_2 = 10 \text{ mA cm}^{-2} \), respectively.

### 3. Results and discussion

The crystal structure and phase composition of all the sintered ceramic samples were studied. Fig. 1 shows the Rietveld refinement profile fits of the XRD patterns for all the samples. The profile fits confirmed the formation of a single CCTO phase (JCPDS 75-2188) in the CCTO and all F\(^-\)-doped CCTO (CCTOF) ceramics. It was found that all the diffraction peaks were well indexed based on the bcc structure within space group \( \text{Im} \overline{3} \). Impurities (e.g., TiO\(_2\), CuO, Cu\(_2\)O and CaTiO\(_3\)) were not seen in the profile fits. The lattice parameters \( (a) \) of all the samples are summarized in Table 1. The \( a \) values of all the samples can be compared to 7.391 Å for un-doped CCTO (JCPDS 75-2188). It is notable that the \( a \) values of CCTOF did not change with F\(^-\) dopant concentration. This result is similar to that reported in previous work with \( \text{CaCu}_3\text{Ti}_4\text{O}_{12-x}\text{F}_x \) where \( x = 0-0.2 \).\(^{38}\) The unchanged lattice parameter was likely because the ionic radii of the substituted F\(^-\) anion \( (r_2 = 1.31 \text{ Å}) \) and the host O\(^2-\) ion \( (r_4 = 1.38 \text{ Å}) \) are not greatly different.\(^{38}\)

Surface morphologies of the CCTO and CCTOF ceramics sintered at 1075 °C for 3 h are shown in Fig. 2. As can be clearly seen, there was abnormal grain growth in the microstructure of the CCTO ceramic, where the large sized grains (≈30–50 μm) were surrounded by small grains (≈5–10 μm). This is generally reported in literature and was ascribed to the liquid phase sintering mechanism.\(^{14,26,32}\) It was found that the mean grain size of CCTO ceramics was greatly enlarged by doping with F\(^-\) anions. Almost all grains of the F0.5, F1.0 and F2.0 samples were very large (≈40–100 μm).

Usually, the grain growth mechanism of a polycrystalline ceramic is associated with mass transport by diffusion of ions (or atoms) across the GB layer. During sintering, the dopant directly melts and/or reacts with a small part of the major phase to form a eutectic liquid. These can cause a formation of a liquid phase in the microstructure. The liquid was present at the contact areas between the particles in the ceramic microstructure. This can contribute to promotion of the diffusion of ions. For polycrystalline ceramics, a liquid phase generally originates from a eutectic liquid. The eutectic temperature for

Fig. 1 | Profile fits for the Rietveld refinements of the XRD patterns of CCTO, F0.5, F1.0 and F2.0 samples.
CuO–TiO₂ is about 950 °C for CCTO ceramics. Although the liquid phase formed by melting of the dopant usually occurs in metallic systems, it is also possible in CCTOF ceramics. This is due to the low melting point of CuF₂ (836 °C). Thus, the formation of a liquid phase is likely caused by these two mechanisms. Enhancement of GB mobility resulted from the presence of the liquid phase(s) and was suggested an important factor for increasing grain growth rate in CCTOF ceramics.

Fig. 3 shows the SEM mapping images of the F05 sample. This result confirms the existence of all major elements (i.e., Ca, Cu, Ti, and O) and confirms the homogeneous dispersion of F⁻ dopant in both of the grains and GBs. Segregation of the F⁻ dopant in any specific region was not seen. In contrast, segregation of Cu was observed along the GBs, which is also generally reported in previous studies. This result strongly confirms that the liquid phase is closely associated with a Cu-rich phase, which likely originated from melting of CuF₂ and the eutectic phase of CuO–TiO₂.

The frequency dependence of the dielectric properties of all the ceramic samples is shown in Fig. 4. ¹ε was slightly dependent on frequency in the range of 10² to 10⁵ Hz. Notably, ¹ε can be enhanced from ≈10⁴ to ≈10⁵ by doping with F⁻ anions. Considering the microstructural change in CCTOF ceramics, the enlarged grain size is one of the most important parameters that increased ¹ε. However, the linear and continuous increase in ¹ε of the F⁻-doped CCTO ceramics was not correlated with their grain sizes. ¹ε increased with increasing anion dopant concentration, but not for the mean grain sizes. Therefore, variation in ¹ε cannot be attributed to the change in the microstructure only. As illustrated in the inset of Fig. 4, a low-frequency tan δ of CCTO ceramics was greatly decreased by doping with F⁻ anions. At 10² Hz, the tan δ of the CCTOF
ceramics was reduced by a factor of 5. At frequencies higher than 10^5 Hz, the frequency dependent behaviors of tan δ for all of the samples were similar, i.e., tan δ increased with increasing frequency. This indicates the dielectric relaxation behavior of primary polarization, which will be discussed below. The ε' and tan δ values at RT and 1 kHz of all the ceramic samples are summarized in Table 1. It is notable that the low-frequency tan δ of the CCTOF ceramics was significantly reduced to <0.1, while ε' greatly increased. Generally, this result is hard to achieve in CCTO ceramics because variations in tan δ and ε' values are usually directly proportional. The ε' and tan δ values of the CCTO and CCTOF ceramics compared to those reported in literature for both of un-doped and metal ions-doped CCTO ceramics prepared by using different method and sintered under various conditions are shown in Table 2.

The dielectric relaxation behavior of CCTO and CCTOF ceramics was studied. As shown in Fig. 5, two dielectric relaxations were observed in distinct frequency ranges. The low-frequency dielectric relaxation likely originated from the sample-electrode effect. The relatively high-frequency dielectric relaxation (i.e., the primary relaxation) has widely been accepted as associated with the IBLC effect, i.e., the Maxwell–Wagner polarization relaxation. The step-like decrease in ε' and relaxation peak of ε'' (ε'' is the imaginary part of the complex dielectric permittivity or dielectric loss, ε'' = ε' × tan δ) shifted to a higher frequency with increasing temperature, indicating a thermally activated relaxation mechanism. The activation energy for dielectric relaxation can be calculated from the critical frequency (f_max) at various temperatures at which the relaxation peak appeared as:

\[ f_{\text{max}} = f_0 \exp \left( \frac{-E_a}{k_B T} \right) \] (2)

where f_0 is the pre-factor, E_a is the activation energy required for relaxation process, T is absolute temperature and k_B is Boltzmann constant. The frequency dependence of f_max for all the samples obeyed the Arrhenius law in eqn (2), inset of Fig. 5(d). The E_a values of the CCTO, F05, F10 and F20 samples were about 0.096, 0.096, 0.099 and 0.115 eV, respectively. These values are comparable to the reported values of 0.103 eV, 0.011 eV (ref. 11) and 0.101 eV. Doping CCTO with F anions into O²⁻ sites has a small influence on the dielectric-relaxation activation energy of CCTO ceramics.

To elucidate the influences of F⁻ anion dopant ions on the dielectric properties of CCTO ceramics, the grain and GB responses were studied using an impedance spectroscopy technique. Fig. 6(a) and (b) show Z* plots for all the samples at RT and 80 °C, respectively. Only the linear part of the semicircular arcs was observed at RT in the frequency range of 10² to 10⁶ Hz. A nonzero intercept on the Z' axis was observed, inset of Fig. 6(a), indicating an electrical response of the semiconducting grains. Thus, the linear part of the semicircular arcs should be due to the electrical response of the GBs. The grain resistance (R_g) values (estimated from the nonzero intercept) of the CCTOF ceramics were smaller than that of the undoped CCTO ceramic by a factor of 2. At RT, R_g of the CCTO sample was ~100 Ω cm, while R_g values of the CCTOF ceramics were nearly the same in value with R_g ~ 50 Ω cm. At RT, it is very difficult (or perhaps impossible) to accurately calculate the value of R_gb in the measured frequency range since just few data points on the full arcs appeared in these Z* plots. The trend of R_gb values for the CCTOF ceramics cannot be determined. To obtain this, a Z* plot at a high temperature should be performed. In Fig. 7(b), the R_gb of each sample was estimated and

found to be significantly increased by doping with F\textsuperscript{-}. \(R_{gb}\) of the CCTOF ceramics was enhanced even through the mean grain size increased compared to that of the CCTO sample. This result gives a significant clue, reflecting the largely enhanced resistance of individual GB layers. This is one of the most important factors contributing to reduction in a low-frequency tan\(\delta\) in CCTOF ceramics [inset of Fig. 4]. Thus, the distribution of dopants near GBs can cause an increase in the GB resistivity, which often make great influence on the low-frequency dielectric properties,\textsuperscript{44} as clearly seen in Fig. 5. It is worth noting that all the samples were electrically heterogeneous, consisting of grains with very small \(R_g\) values and very high values of \(R_{gb}\). Therefore, it is reasonable to suggest that the giant dielectric response in CCTOF ceramics originated from the IBLC effect.

\(R_g\) and \(R_{gb}\) values can be calculated in various temperatures. The conductivities of the grain (\(\sigma_g\)) and GB (\(\sigma_{gb}\)) were calculated from \(R_g\) and \(R_{gb}\), respectively. As demonstrated in Fig. 6(c) and (d), the temperature dependencies of \(\sigma_g\) and \(\sigma_{gb}\) follow the Arrhenius law:

\[
\sigma_{gb} = \sigma_0 \exp \left( \frac{-E_{gb}}{k_B T} \right) \quad \text{and} \quad \sigma_g = \sigma_0 \exp \left( \frac{-E_g}{k_B T} \right) \quad \text{Eqn. (3)}
\]

where \(\sigma_0\) is a constant value and \(E_g\) and \(E_{gb}\) are the conduction activation energies inside the grains and GBs, respectively. The \(E_{gb}\) values of the CCTO, F05, F10 and F20 samples were about 0.630, 0.696, 0.714 and 0.739 eV, respectively. The \(E_g\) values for all the samples are summarized in Table 1. \(E_g\) slightly increased with increasing F\textsuperscript{-} dopant concentration. It was observed that the trends of variation in \(E_g\) and \(E_{gb}\) values were similar. According to the Maxwell–Wagner polarization relaxation model, the temperature dependence at the critical frequency, \(f_{max}\), of a thermally activated relaxation process can be expressed in term of \(R_g\), as the following:\textsuperscript{13,21}

\[
f_{max} \approx \left(2\pi R_g C_{gb}\right)^{-1} \approx \left(2\pi C_{gb}\right) \left(R_g\right)^{-1} \exp \left(\frac{-E_g}{k_B T}\right) \quad \text{Eqn. (4)}
\]

where \(C_{gb}\) is the capacitance of GBs. From eqn (2), the temperature dependence of \(f_{max}\) for the dielectric relaxation process in CCTO and CCTOF ceramics follows the temperature dependence of the conduction process of the grains, since \(C_{gb}\) is nearly independent of temperature. According to eqn (2)–(4), the activation energies required for electrical conduction in the grain interiors and for dielectric relaxation process should be the very close. Thus, the calculated \(E_g\) and \(E_{gb}\) values strongly confirm that the giant dielectric response in CCTOF ceramics can be attributed to the Maxwell–Wagner polarization based on the IBLC structural model.

As shown in the inset of Fig. 6(a), \(R_g\) of CCTO ceramics was reduced by doping with F\textsuperscript{-} anions, indicating an increase in the concentration of free charge carriers in the grain interiors. To clarify the effect of F\textsuperscript{-} doping on the electrical properties of the grains, variation in valence states of Cu\textsuperscript{2+} and Ti\textsuperscript{4+} ions in CCTO...
and CCTOF samples was investigated using XPS and XANES techniques. As illustrated in Fig. 7(a) and (c), the main XPS peaks at \( \approx 933 \) eV for the CCTO and F10 samples confirm the existence of large numbers of Cu\(^{2+}\) ions.\(^{9,28,32}\) The Cu 2p\(_{3/2}\) region can be divided into three peaks using Gaussian–Lorentzian profile fitting. The small XPS peaks at relatively lower and higher binding energies at \( \approx 931 \) and \( \approx 936 \) eV indicated the existence of Cu\(^{+}\) and Cu\(^{3+}\), respectively.\(^{9,28,32}\) The Cu\(^+/\)Cu\(^{2+}\) ratios of the CCTO and F10 samples were, respectively, about 4.26% and 5.65%, while their respective Cu\(^{3+}/\)Cu\(^{2+}\) ratios were 13.62% and 27.22%. Doping CCTO with F caused an increase in both Cu\(^{+}\) and Cu\(^{3+}\) concentrations.

In addition to Cu\(^{+}\) and Cu\(^{3+}\), the presence of Ti\(^{3+}\) ions is usually considered a major cause of the formation of n-type semiconducting grains in CCTO ceramics. As depicted in Fig. 7(b) and (d), the primary XPS peak at \( \approx 458 \) eV for Ti\(^{4+}\) was confirmed in all the samples. Unfortunately, the presence of Ti\(^{3+}\) cannot be modeled using Gaussian–Lorentzian profile fitting. This may be due to a small amount of Ti\(^{3+}\) in both the samples.\(^{2}\) Thus, XANES was used to further investigate the existence of Ti\(^{3+}\). Fig. 8 shows normalized Ti K-edge XANES spectra of the CCTO and F10 samples as well as the standard TiO\(_2\) (Ti\(^{4+}\)) and Ti\(_2\)O\(_3\) (Ti\(^{3+}\)) samples. It was found that the position of the edge energy of both samples was very close to the TiO\(_2\) standard. As expected, a small amount of Ti\(^{3+}\) was confirmed to exist. To obtain the ratios of Ti\(^{3+}/\)Ti\(^{4+}\), the edge value was calculated from the maximum value of the first derivative in the edge region.\(^{35}\) The ratio of Ti\(^{3+}/\)Ti\(^{4+}\) can be calculated from the energy edge value.\(^{39}\) The ratios of Ti\(^{3+}/\)Ti\(^{4+}\) in the CCTO and F10 samples were found to be 0.82% and 2.46%, respectively.

Substitution of O\(^{2-}\) with F\(^-\) anions requires charge compensation, which can be achieved by reduction in cation valence (Cu\(^{2+}\) \(\rightarrow\) Cu\(^{+}\) and Ti\(^{4+}\) \(\rightarrow\) Ti\(^{3+}\)). This charge compensation behavior is similar to that observed in the case of Y\(^{3+}\)-doped-CCTO ceramics, which \( R_g \) of CCTO was reduced by doping with Y\(^{3+}\).\(^{45,46}\) It is worth noting that the Cu\(^{3+}/\)Cu\(^{2+}\) ratio of the F10 sample was significantly increased. As shown in the SEM-mapping image for Cu dispersion, Fig. 3, segregation of Cu-rich phase along the GBs was observed. This indicated the decomposition of CuO from the CCTO lattice, creating cation vacancies. Therefore, it is possible that the increased Cu\(^{3+}/\)Cu\(^{2+}\) ratio of the F10 sample might be due to the creation of Cu vacancies.\(^{9}\)

Generally, the conductivity of n-type semiconducting grains is elevated by increasing the number of free electrons. Thus, the reduction in \( R_g \) of the CCTOF samples should be correlated with the increase in Cu\(^{3+}/\)Cu\(^{2+}\) and Ti\(^{3+}/\)Ti\(^{4+}\) ratios over those found in the CCTO sample. For p-type semiconductor CuO ceramics, conduction is primarily caused by hole hopping between Cu\(^{2+}\) \(\leftrightarrow\) Cu\(^{+}\). The increase in the Cu\(^{3+}/\)Cu\(^{2+}\) ratio may also be an important cause of the reduced \( R_g \). Form this point of view, hopping of charge carriers between Cu\(^{+}\) \(\leftrightarrow\) Cu\(^{3+}\), Cu\(^{3+}\) \(\leftrightarrow\) Cu\(^{2+}\), and Ti\(^{3+}\) \(\leftrightarrow\) Ti\(^{4+}\) sites in the CCTO structure can result in
electrical conductivity. According to our previous report, we found that the variation in \( R_g \) of Na\(_{0.5}\)Y\(_{0.5}\)Cu\(_3\)Ti\(_4\)O\(_{12}\) ceramics was only consistent with a change in the Ti\(^{3+}/\)Ti\(^{4+}\) ratio, whereas changes in Cu\(^+\)/Cu\(^{2+}\) and Cu\(^{3+}/\)Cu\(^{2+}\) ratios was not correlated to \( R_g \) values.\(^{37}\) The conduction mechanism inside the n-type semiconducting grains might be primarily attributed to electron hopping from a Ti\(^{3+}\)–O–Ti\(^{4+}\) to a Ti\(^{4+}\)–O–Ti\(^{3+}\). Hopping of charge carriers between complex defects, i.e., Cu\(^+\)–O–Cu\(^{2+}\) ↔ Cu\(^{3+}\)–O–Cu\(^{+}\), was likely difficult owing to much different valance states of Cu\(^+\) and Cu\(^{3+}\).

The effect of F\(^-\) anions on the non-ohmic properties of CCTO ceramics is illustrated in Fig. 9. All the samples exhibited nonlinear \( J-E \) characteristics. Accordingly, \( E_b \) and \( \alpha \) values were calculated and summarized in Table 1. According to the improved dielectric properties and the observed nonlinear electrical properties of CCTOF ceramics, it was suggested that the sample could be applied as capacitor-varistors.\(^{48}\) \( \alpha \) values for all the samples were not significantly different, while \( E_b \) values of the CCTOF samples were greater than that of the undoped CCTO sample, even though their grain sizes were larger than those of the CCTO sample. The volume fraction of the GB, which is inversely proportional to its mean grain size, was decreased by doping with F\(^-\) anions. The increase in \( E_b \) of the CCTOF samples was consistent with their enhanced \( R_{gb} \) values over that of the CCTO sample. Although the volume fraction of the GB in the CCTOF samples was lower than that of the CCTO sample, the total resistance of their GBs (\( R_{gb} \)) and \( E_b \) were larger.
Thus, the resistivity of an individual GB layer of the CCTOF samples should much be larger than that of the CCTO sample. These results indicate that the intrinsic property (i.e., potential barrier height) of the GB of CCTO ceramics was enhanced by F⁻ doping. It was reasonably proposed that based on the n-type semiconducting grains of CCTO ceramics, the electronic energy band structure across the GB layer was equivalent to n-i-n. Double Schottky potential barriers can be created at interfaces between n-type grains caused by trapping at acceptor states. This resulted in the bending of the conduction band across the GB. A potential barrier (Φ_gb) was created at the GB sandwiched by n-type semiconducting grains. In the absence of a DC bias, Φ_gb can be expressed as:

\[ Φ_gb = \frac{qN_a^2}{8ε_0ε_rN_d}, \]

where \( N_a \) is the acceptor (surface charge) concentration, \( ε_r \) is the relative permittivity of materials, \( N_d \) is the charge carrier concentration in the semiconducting grains and \( q \) is the electronic charge. It was reported that the activation energy for conduction at the GBs has a close relationship with the potential barrier height at the GBs. Enhanced \( E_{gb} \) and \( Φ_gb \) were nearly the same in value. As shown in Fig. 6(d) and Table 1, the enhanced \( E_{gb} \) values indicated an increase in Φ_gb. As demonstrated in the inset of Fig. 6(a), \( R_g \) or \( σ_g \) of all the CCTOF samples was smaller than that of the CCTO sample, indicating that the charge carrier concentration in the semiconducting grains (\( N_d \)) of the CCTOF samples was higher. This is responsible for the observed increase in the potential barrier height at the GBs in the CCTOF ceramic samples. Generally, it was observed that the mechanism of potential barrier formation in CCTO ceramics was also correlated with oxygen enrichment at the GBs. For this point of view, it was proposed that the GB region may possess a p-type semiconductor nature, resulting from high oxygen content and/or vacancies of metal ions along the GBs compared with the n-type semiconductor nature inside the grains. For CCTOF ceramics, the creation of oxygen vacancies may possibly be inhibited (or decreased) by F⁻ doping anions due to the lower valence state of the dopant, retaining the p-type semiconductor nature of the GBs and potential barrier height. Thus, substitution of F⁻ anions not only decreased the possibility of a reduction in Φ_gb as a result of creation of oxygen vacancies, but it also enhanced Φ_gb resulting from the creation of free charges inside the semiconducting grains.

Substitution of F⁻ anions into CCTO ceramics can simultaneously improve the electrical properties of the grains and GBs. These can cause increases in both of the free charge carrier concentration inside the semiconducting grains and Schottky barrier height at the GBs, respectively. Under an applied electric field, more charges accumulated at the interface between the semiconducting grain and GB layer due to a high concentration of free charges inside the grain producing a stronger intensity of interfacial polarization (Maxwell–Wagner polarization). This gave rise to a large increase in \( ε' \). Enhanced Φ_gb resulting in \( R_gb \) is the major cause the reduced low-frequency tan δ.

4. Conclusions

Significantly improved giant dielectric properties of CCTO ceramics via simultaneously tuning the electric properties of the grains and GBs was successfully done by doping CCTO with F⁻ anions. The grain size of CCTO ceramics was thus enlarged. The low-frequency tan δ of F⁻-doped CCTO ceramics was greatly reduced by a factor of 3 compared to that of the undoped CCTO ceramic, which was attributed to a large increase in \( R_gb \) and potential barrier height at the GBs. These results were confirmed by the slight increase in electric breakdown strength of F⁻-doped CCTO ceramics, even though the mean grain size was greatly increased. According to the XPS and XANES results, it was shown that the charge carrier concentration inside the semiconducting grains of F⁻-doped CCTO ceramics was increased corresponding to the observed reduction in \( R_gb \). This was responsible for the observed increase in \( ε' \) from \( ≈10^4 \) to \( ≈10^5 \) at 1 kHz due to the increased intensity of interfacial polarization at the GBs. Maxwell–Wagner polarization relaxation based on the internal barrier layer capacitor model of Schottky barriers at the GBs can be used to clearly explain the variations of the giant dielectric behavior and nonlinear electrical properties of F⁻-doped CCTO ceramics.
