Protective effects of Shanxi aged vinegar against hydrogen peroxide-induced oxidative damage in LO2 cells through Nrf2-mediated antioxidant responses

Ting Xia, Jiahui Yao, Jin Zhang, Yu Zheng, Jia Song and Min Wang*

Shanxi aged vinegar (SAV), a kind of typical fermented food, is one of the famous traditional vinegars in China. In this study, the antioxidant properties and hepatoprotective mechanisms of SAV on hydrogen peroxide (H₂O₂)-induced oxidative stress were investigated. Total phenolic, flavonoid contents and browning index were increased during the aging process. Gallic acid was the main component of the phenolic compounds in SAV-5. SAV-5 showed the highest antioxidant activities among all the samples. In addition, H₂O₂ was used to treat human normal hepatocyte LO2 as an inducer of oxidative stress models. Pretreatment with SAV-5 inhibited H₂O₂-induced cytotoxicity and reactive oxygen species (ROS) generation, and alleviated loss of mitochondrial membrane potential in LO2 cells. These pretreatments also significantly increased superoxide dismutase (SOD), catalase (CAT) activities and glutathione (GSH) levels. The results demonstrated that SAV-5 had a significant antioxidant effect, which could prevent oxidative damage in LO2 cells effectively. Finally, SAV-5 activated nuclear factor erythroid-2-related factor 2 (Nrf2) and up-regulated NAD(P)H quinone oxidoreductase 1 (NQO1) and heme oxygenase (HO-1) protein expression in H₂O₂-treated LO2 cells. The protective effects of SAV against H₂O₂-induced oxidative damage in LO2 cells are mainly mediated by the activation of the Nrf2 antioxidant pathway. This study explored the fermented food products with antioxidant activities and the possible hepatoprotective mechanism of traditional Chinese vinegar against oxidative damage in liver cells.

Introduction

Traditional vinegars are typical fermented foods, which have been produced by the process of spontaneous fermentation for centuries.¹ Both grain vinegars and fruit vinegars are fermented products, and contain large amounts of active compounds.² Shanxi aged vinegar (SAV), a well-known traditional Chinese vinegar, is brewed by traditional solid-state fermentation technology.³ During the process, it can produce rich nutrients and functional factors, which provide health and therapeutic effects.⁴ Among these bioactive components, such as phenols, flavonoids and melanoidins, are the main antioxidant ingredients of SAV.⁵ It has been reported that these antioxidants play a crucial role in the prevention of many diseases such as cardiovascular disease, hepatic damage, neurodegenerative diseases, cancer and ageing, because of their capacity for capturing, deactivating or repairing the damage caused by the free radicals that is implicated in such diseases.⁶ Recently, the

antioxidant activities and health properties of vinegar have become the focus of extensive research.

Liver is a vital organ and plays a major role in metabolism, excretion and detoxification in the human body. Liver functions would be impaired by different factors such as infection, drugs, excessive intake of ethanol, causing accumulation of free radicals.⁷ Oxidative stress and liver injury are strongly associated. Oxidative stress is believed to play an important role in the pathogenesis of liver injury.⁸ Prevention or impairment of oxidative stress constitutes a therapeutic target to be achieved for hepatoprotection. Oxidative stress is a state of imbalance between the production of reactive oxygen species (ROS) and the cellular antioxidant defense neutralizing the reactive intermediates and triggering damage.⁹ Overproduction of ROS results in oxidative stress, a deleterious process that can be an important mediator of damage to cell structures, including lipids and membranes, proteins and DNA.¹⁰ The detoxication of ROS is accomplished *via* several enzymatic and non-enzymatic antioxidant mechanisms.¹¹

Nuclear factor erythroid-2-related factor 2 (Nrf2) is a crucial transcription factor mediating protection against oxidants.¹² Under normal conditions, Nrf2 is generally inactivated in the cytoplasm by binding of Kelch-like ECH-associated protein 1

Key Laboratory of Industrial Fermentation Microbiology, Ministry of Education, College of Biotechnology, Tianjin University of Science and Technology, Tianjin, P. R. China. E-mail: mimw@tust.edu.cn; Fax: +86-22-60602298; Tel: +86-22-60601256

(Keap 1). Upon stimulation by stimuli or antioxidants, Nrf2 releases from the Keap 1/Nrf2 complex and translocates to the nucleus. Then, Nrf2 binds to antioxidant-response elements (AREs) to activate the expression of downstream genes, such as heme oxygenase-1 (HO-1), NAD(P)H quinone oxidoreductase 1 (NQO1), and γ -glutamylcysteine synthetase (GCS). These genes constitute a defense system to eliminate ROS, and play an important role in protecting cells against oxidative stress.^{13,14}

SAV is rich in antioxidant compounds that are supplied from raw materials and microbial fermentation.¹⁵ Recent studies have demonstrated that antioxidant activities of traditional balsamic vinegar (TBV) were due to their phenolic, flavonoid contents and melanoidins.^{16,17} These antioxidant ingredients interact with each other and together contribute to the total antioxidant capacity of vinegar. However, antioxidant components of SAV with different aging time, have been rarely explored. Meanwhile, both grain vinegars and fruit vinegars can improve antioxidant abilities and reduce oxidative damage.^{18,19} It has been reported that vinegar could protect liver cells against oxidative damage *in vivo*. Antioxidant activities of vinegar may play an important role in prevention of liver damage.^{20,21}

In the present study, antioxidant components and antioxidant capacity of SAV with different aging time were investigated. Then, the effects of SAV on cell viability, intracellular ROS level, mitochondrial membrane potential, and antioxidant defense systems were measured in H₂O₂-treated LO2 cells. Furthermore, the expression of Nrf2 and downstream genes were detected by western blotting to explore the antioxidant pathway of SAV. These findings would clarify the antioxidant properties and hepatoprotective mechanisms of SAV, and provide a kind of functional food against oxidative damage in human liver cells.

Experimental

Chemicals and reagents

Folin–Ciocalteu reagent, 2,2-diphenyl-1-picrylhydrazyl (DPPH), gallic acid and rutin were obtained from Sinopharm Chemical Reagent Co., Ltd (Shanghai, China). Total antioxidant capacity assay kit with 2,2'-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) and ferric reducing antioxidant power (FRAP) were purchased from Beyotime Institute of Biotechnology (Shanghai, China). Hydrogen peroxide (H₂O₂, 35 wt%) was purchased from Alfa Aesar (Johnson Matthey Co. Lancaster, UK). Superoxide dismutase (SOD), catalase (CAT), glutathione (GSH), malonaldehyde (MDA) and protein assay kits were obtained from Nanjing Jiancheng Bioengineering Institute (Nanjing, China).

The primary antibodies against rabbit Nrf2, NQO1, HO-1 and the secondary horseradish peroxidase (HRP)-labeled goat-anti-rabbit antibodies, were purchased from Abcam (Cambridge, UK). Antibody against rabbit β -actin was purchased from Bioworld Technology (Nanjing, China).

Samples and cell culture

Vinegar samples, including SAV and Shanxi vinegar (SV), were purchased from local supermarkets. Human normal liver cell

line LO2 was purchased from Cell Bank of Chinese Academic of Science (Shanghai, China). Cells were cultured at 37 °C and 5% CO₂ in RPMI-1640 medium (Hyclone, Logan, Utah, USA), supplemented with 10% fetal bovine serum (FBS, Gibco, Grand Island, NY, USA), penicillin/streptomycin (1 : 100, Hyclone). Cells were treated with SAV at different concentration (0–10 μ L mL⁻¹). 20 mM HEPES buffer was used to buffer the medium. Culture medium was changed every 2 days.

Extraction and determination of high molecular weight melanoidins

High molecular weight (>10 kDa) melanoidins were extracted from vinegar samples. Different vinegar samples of 1 mL were diluted to 10 mL with distilled water and then filtered (Whatman filter papers 40, Whatman, Maidstone, UK). One aliquot (4 mL) of each filtered sample was subjected to ultra-filtration with Amicon Ultra-4, regenerated cellulose 10 kDa (Millipore, MA, USA) at 7500 g for 20 min at 4 °C. The retentate, containing high molecular weight melanoidins and the filtrate containing low molecular weight compounds, such as phenols and flavonoids, were separated. The amount of high molecular weight melanoidins was determined as browning index by measuring the color as absorbance at 420 nm in a 1 cm glass cuvette. The samples were diluted in distilled water to give appropriate absorbance values. The filtrate was used to analyze for the total phenolic and flavonoid contents.

Determination of total phenolic and flavonoid contents

Total phenolic content of the filtrate was determined by the Folin–Ciocalteu method. The value for total phenolic content was expressed in terms of the gallic acid equivalent (mg mL⁻¹). An appropriately diluted sample (0.2 mL) was added sequentially with Folin–Ciocalteu reagent (0.8 mL), 1.5 mL of 10% sodium carbonate. The mixture was diluted to 10.0 mL with distilled water and incubated at room temperature in the dark for 2 h. Absorbance was measured at 765 nm using spectrophotometry. Phenolic concentration was based on a standard curve of gallic acid. The total phenolic content was expressed as gallic acid equivalent (mg GAE per mL).

Total flavonoid content the filtrate was measured through a colorimetric assay. The value for total flavonoid content was expressed in terms of the rutin equivalent (mg mL⁻¹). An appropriately diluted sample (2.0 mL) was added to a flask and then NaNO₂ (1.0 mL, 50 g L⁻¹) was added immediately. After standing for 6 min, Al(NO₃)₃ (1.0 mL, 50 g L⁻¹) was added and the mixture was left to stand for another 6 min before 5 M NaOH (4.0 mL) was added. The solution was diluted to 25.0 mL with distilled water and kept at room temperature in the dark for 15 min. Absorbance was measured at 510 nm using spectrophotometry. Flavonoid concentration was estimated using a standard curve of rutin. The total flavonoid content was expressed as rutin equivalent (mg RE per mL).

Analysis of phenolic compounds by high-performance liquid chromatography (HPLC)

A high-performance liquid chromatography (HPLC) was used for identification and quantification of phenolic compounds in vinegar samples. SAV-5 sample (5.0 mL) was mixed with 15 mL ethyl acetate and then centrifuged at 5000 rpm for 10 min. The extraction was concentrated using rotary evaporation instrument (35–40 °C) and dissolved with 2 mL methanol. The solution was filtered using a 0.45 µm Millipore membrane and injected into HPLC system (Agilent Technologies Inc., California, USA). Chromatographic separation was performed using a reverse phase column (Luna C18 (2), 250 × 4.6 mm, 4 µm, Phenomenex, Torrance, CA). A non-linear gradient elution of water containing 0.1% acetic acid (A) and acetonitrile (B) was used as follows: A/B (95 : 5) to (30 : 70) at 40 min, (20 : 80) at 45 min, (100 : 0) at 50 min, (95 : 5) at 51 min, and then held for 5 min. The flow rate was 1.00 mL min⁻¹, the injection volume was 20 µL, and the detection wavelength was 278 nm.

Determination of total antioxidant capacity *in vitro*

DPPH assay. The free-radical-scavenging activities of vinegar samples were measured by the DPPH assay. Briefly, 20 µL of an appropriately diluted sample was added to 180 µL of DPPH working solution and incubated at room temperature in the dark for 30 min. The absorbances were measured at 517 nm in an automated enzyme-linked immunosorbent assay (ELISA) reader (Tecan, Salzburg, Austria). Trolox was used as a reference compound.

ABTS assay. This assay was based on the ability of different substances to scavenge the ABTS radical cation (ABTS⁺). ABTS⁺ was produced by ABTS stock solution and oxidant solution. The working solution was prepared by mixing the two stock solutions and allowing them to react completely in the dark at room temperature for 12 h before use. 10 µL of an appropriately diluted sample was added to 170 µL of ABTS working solution and incubated at room temperature in the dark for 6 min. The absorbances were measured at 414 nm in an ELISA Plate Reader. Trolox was used as a reference compound.

FRAP assay. The reducing ability of vinegar samples was measured by FRAP assay. A working solution was freshly prepared by mixing 300 mM acetate buffer, 10 mM TPTZ, and 20 mM FeCl₃ at a ratio of 10 : 1 : 1. The solution was kept at 37 °C in the dark. 5 µL of an appropriately diluted sample was added to 180 µL of FRAP working solution and incubated at room temperature for 5 min. The absorbances were measured at 593 nm in an ELISA Plate Reader. Trolox was used as a reference compound.

Cell viability assay

Cell viability was determined by Cell Counting Kit-8 (CCK-8, Dojin Laboratories, Kumamoto, Japan) colorimetric method. Cells (5 × 10⁴ per mL) were cultured in a 96-well (100 µL per well) microplate at 37 °C in humidified 5% CO₂ for 24 h, and treated with ligands for required time. After treatment, cells were added with 10 µL CCK-8 solution, and incubated for 3 h at

37 °C. Absorbance in each well was quantified at 450 nm using an ELISA reader.

Measurement of intracellular ROS generation

The formation of intracellular ROS was measured using a fluorescent probe, 2',7'-dichlorofluorescein-diacetate (DCFH-DA, Sigma-Aldrich, St. Louis, MO, USA). LO2 cells were cultured in 6-well plates for 24 h, and treated with ligands for required time. After treatment, cells were added with 10 µM DCFH-DA and incubated for 30 min in the dark. Nonfluorescent DCFH-DA dye was freely penetrated into cell membrane and enzymatically hydrolyzed by intracellular esterase to 2',7'-dichlorodihydrofluorescein (DCFH). Then DCFH was rapidly oxidized to form highly fluorescent 2',7'-dichlorofluorescein (DCF) in the presence of ROS. The DCF fluorescence intensity is believed to be parallel to the amount of ROS formed intracellularly. Cells were collected and resuspended with phosphate buffer saline (PBS). The fluorescence intensity was determined by flow cytometry within 1 h.

Determination of mitochondrial membrane potential

Fluorescent probe JC-1 (Sigma-Aldrich, St. Louis, MO, USA) was used to estimate mitochondrial membrane potential. Cells were cultured in 6-well plates and treated with different ligands. Cells were washed twice with PBS and stained with JC-1 in the dark for 30 min at 37 °C in humidified 5% CO₂ in complete medium. After incubation, cells were washed twice with PBS and immediately observed under a fluorescence microscopy within 1 h.

Determination of antioxidant enzymes and GSH and lipid peroxidation

Antioxidant enzymes (CAT and SOD) and non-enzymatic antioxidant (GSH) in liver cells were measured using commercial kits according to the enclosed guidelines. The absorbance of each well was measured by an ELISA reader or spectrophotometry. SOD and CAT levels were expressed as U per mgprot, and GSH level was expressed as µmol per gprot.

MDA, a break down product of the oxidative degradation of cell membrane lipids, has been generally considered as an indicator of lipid peroxidation. Lipid peroxidation in liver cells was determined by a MDA assay reagent kit according to the manufacturer's instruction. Lipid peroxidation level was assayed by the measurement of thiobarbituric acid-reactive substance (TBARS) level and was expressed as MDA level. The spectrophotometric absorbance was assessed at 532 nm using spectrophotometry. The MDA level was expressed as nmol per mgprot.

Western blot analysis

After treatment, cells were collected and lysed for 30 min in RIPA buffer. The concentration of protein was measured by BCA reagent. For each sample, 20 µg of total protein extracts were diluted in SDS-sample buffer, denatured at 98 °C for 5 min and separated with a 12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gel. After electrophoresis, the

proteins were transferred to a polyvinylidene fluoride (PVDF) membrane (Millipore, MA, USA). The membrane was blocked with 5% milk for 1 h in TBST (20 mM Tris-HCl, pH 7.4, 150 mM NaCl, 0.1% Tween-20), and incubated overnight with primary antibodies. After washing with TBST, the membranes were incubated with horseradish peroxidase-conjugated secondary antibodies for 1 h at room temperature and washed. The immunoreactive bands were detected using an enhanced chemiluminescence (ECL, Thermo Scientific, Vantaa, Finland). Each membrane was stripped and re-probed with anti-actin antibody to ensure equal protein loading.

Statistical analyses

Results were presented as mean \pm standard deviation (S.D.). Analysis of variance was performed by one-way ANOVA procedures, using Prism 5.03 (GraphPad Software Inc., San Diego, CA, USA). Significant differences were calculated according to the Bonferroni post hoc test. A P -value < 0.05 was considered statistically significant.

Results and discussion

Total phenolic, flavonoid contents and browning index

Phenols, flavonoids and melanoidins were considered the main bioactive compounds and had antioxidant properties in food.^{22–24} It has been reported that these antioxidant compounds were indicated to a powerful scavenging ability of free radicals and had a significant contribution to free radical-induced disease.^{25–27} As shown in Table 1, total phenolic content was determined by Folin-Ciocalteu reagent. The concentration of phenolics ranged between 0.665 ± 0.020 mg GAE per mL and 3.265 ± 0.278 mg GAE per mL. A significant difference was found in total phenolic content between the two samples ($P < 0.05$). The phenolic content of SAV-5 was the highest among all the vinegar samples. Total flavonoid content was determined using spectrophotometric method with aluminum chloride. The concentration of flavonoids in different samples was in the range of 0.446 ± 0.070 mg RE per mL to 3.008 ± 0.063 mg RE per mL. The flavonoid content of SAV-5 was significantly higher than that of other samples ($P < 0.05$). The results suggest that total phenolic and flavonoid contents are increased in a time-dependent manner. In

addition, the browning index (A420 nm) of high molecular weight melanoidins ranged between 0.528 ± 0.010 and 1.245 ± 0.059 . There was no significant difference in the browning index between SAV-5 (1.236 ± 0.029) and SAV-4 (1.245 ± 0.059). The browning index of SAV-4 and SAV-5 significantly was higher than that of other samples ($P < 0.05$). This increment in the browning index indicates that the Maillard reaction continues during aging process of 5 years, being favored by the synthesis of new polymeric compounds.

Major phenolic compounds of SAV-5

Major phenolic compounds of SAV-5 were analyzed by HPLC. As shown in Table 2, these compounds were identified as gallic acid, catechins, chlorogenic acid, caffeic acid, syringic acid, p-coumaric acid, ferulic acid and rutin. The concentration of gallic acid was 114.67 ± 3.88 mg L⁻¹, followed by catechins (86.98 ± 0.36 mg L⁻¹) and caffeic acid (53.69 ± 1.87 mg L⁻¹), which exhibited antioxidant activities and possessed a protective effect against oxidative damage.²⁸ The results indicate that gallic acid is the main component of the phenolic compounds in SAV-5.

Total antioxidant capacity *in vitro*

DPPH and ABTS are both stable free radicals, which are used for the antioxidant activities test.²⁹ FRAP measures the reducing capability based upon the ferric ion, which is used for another

index for evaluating the antioxidant activities.³⁰ *In vitro* studies have shown that the antioxidant activity of TBV measured by DPPH and ABTS were $13.59 \pm 6.6 \mu\text{M TE}$ s per mL and $33.52 \pm 19.3 \mu\text{M TE}$ s per mL, respectively.³¹ In this study, total antioxidant activities of vinegar samples were evaluated by DPPH, ABTS and FRAP assays. Scavenging activity of trolox was used as the standard.³² DPPH, ABTS and FRAP units of vinegar samples were calculated as trolox equivalent antioxidant capacity (TEAC). As shown in Table 3, the TEAC values of vinegar samples in DPPH assay were gradually increased with the aging time. The radical scavenging ability of vinegar in ABTS and FRAP assays showed the antioxidant capacity similar to that in DPPH assay. Meanwhile, the results showed that the TEAC values of SAV-5 in DPPH, ABTS and FRAP assays were 24.29 ± 1.81 TEAC, 13.54 ± 0.22 TEAC, 18.65 ± 0.11 TEAC, respectively, which were significantly higher than those of other samples ($P < 0.05$). The results imply that SAV-5 can efficiently scavenge various free radicals in different assays and exhibit the highest antioxidant activity *in vitro*. Then, SAV-5 was selected for evaluation of the potential protective effects in LO2 cells.

SAV-5 protected LO2 cells against H₂O₂-induced cytotoxicity

In order to eliminate the interference of acetic acid, 20 mM HEPES buffer was used to buffer the medium.³³ The effects of

SAV-5 on cell viability in human liver cells were investigated by CCK-8 assay. LO2 cells were treated with increasing concentrations of SAV-5 for 24 h. As shown in Fig. 1A, cell viability was not significantly changed when LO2 cells were treated with 2.5–10 $\mu\text{L mL}^{-1}$ vinegar. These results suggest that vinegar has no cytotoxic effect on human normal liver cells at the selected concentrations.

A reliable *in vitro* cellular model for the study of oxidative damage has been proved invaluable experimental tools in basic research.³⁴ H₂O₂ is a major component of ROS, which is used extensively as an inducer in oxidative stress models.³⁵ In this study, we used H₂O₂ to establish an oxidative injury cell model. LO2 cells were exposed to H₂O₂ at different concentrations (0–400 μM) for 6 h. As shown in Fig. 1B, survival of LO2 cells was significantly decreased in a dose-dependent manner. Cell viability was reduced to $61.01 \pm 4.38\%$ in 200 μM H₂O₂-treated group. According to previous studies, H₂O₂-injured cellular models were established as the cell viability reduced to 50–70%.³⁶ Therefore, treatment of 200 μM H₂O₂ for 6 h was chosen for further experiments.

Next, we evaluated the potential protective effects of SAV-5 against oxidative stress-induced injury in LO2 cells. Cells were pretreated with various concentrations of vinegar and 10 $\mu\text{g mL}^{-1}$ vitamin C for 24 h, and then H₂O₂-induced cytotoxicity in LO2 cells was investigated. Vitamin C, a highly effective antioxidant, is often used as positive control to protect cells against H₂O₂-induced cell death.³⁷ As shown in Fig. 1C, after exposure to 200 μM H₂O₂ for 6 h, cell viability was significantly decreased compared to the control group. However, pretreatment with SAV-5 attenuated H₂O₂-induced cell death in a dose-dependent manner. 10 $\mu\text{L mL}^{-1}$ SAV-5 and 10 $\mu\text{g mL}^{-1}$ vitamin C restored cell viability up to $91.73 \pm 4.41\%$ and $86.40 \pm 4.35\%$, respectively. At 10 $\mu\text{L mL}^{-1}$, the protective effect of SAV-5 was similar to that of 10 $\mu\text{g mL}^{-1}$ vitamin C. 10 $\mu\text{L mL}^{-1}$ SAV-5 showed the best protective effect comparable to other concentrations of vinegar. These results indicate that SAV-5 can ameliorate H₂O₂-induced cytotoxicity and exhibit hepatoprotective activity in LO2 cells.

SAV-5 inhibited H₂O₂-induced ROS generation and lipid peroxidation in LO2 cells

ROS are by products of aerobic metabolism, which is often associated with the principle of oxidative stress.³⁸ Oxidative

Fig. 1 Protective effects of SAV-5 against H₂O₂-induced cell death in LO2 cells. (A) LO2 cells were treated with various concentrations of vinegar for 24 h. (B) Cells were treated with increasing concentrations of H₂O₂ for 6 h. (C) Cells were pretreated with various concentrations of vinegar and 10 $\mu\text{g mL}^{-1}$ vitamin C for 24 h, and then treated with 200 μM H₂O₂ for 6 h. Vitamin C was used as positive control. Cell viability was measured by CCK-8 assay. Data are presented as mean \pm S.D. ($n = 3$) for each group. ** $p < 0.01$, *** $p < 0.001$.

stress is the net result of an imbalance between production and destruction of ROS, which is involved in over 100 diseases, as their cause or consequence.^{39,40} To evaluate the levels of intracellular ROS in H₂O₂-treated LO2 cells, a DCFH-DA fluorescent probe was used. The results showed that the DCF fluorescence intensity in H₂O₂-treated group was significantly increased to 189.80 ± 15.34% compared with that in the control group. However, the fluorescence intensity was notably reduced to 146.32 ± 14.98% and 121.41 ± 13.16%, respectively, in LO2 cells pretreated with 5 μL mL⁻¹ and 10 μL mL⁻¹ vinegar. Pretreatment with 10 μL mL⁻¹ SAV-5 showed the highest scavenging activity of intracellular ROS (Fig. 2A and B). Exogenous H₂O₂ treatment results in accumulation of intracellular ROS, which play an important role in cell death, differentiation, contraction and cell proliferation.⁴¹ These results imply that pretreatment with SAV-5 can inhibit H₂O₂-induced ROS generation and protect the cells from intracellular ROS damage.

MDA, a degradation product of membrane lipid peroxidation, is one of the primary events in oxidative damage. MDA level is commonly known as a marker of oxidative stress.⁴² As shown in Fig. 2C, accompany with ROS generation, MDA level in H₂O₂-treated group was also significantly increased compared with that in the control group. However, pretreatment with 5 μL mL⁻¹ and 10 μL mL⁻¹ vinegar markedly suppressed the overproduction of MDA level in H₂O₂-treated LO2 cells.

Pretreatment with 10 μL mL⁻¹ SAV-5 showed the strongest inhibitory effect with MDA level decreasing to 6.872 ± 1.117 nmol mg⁻¹ protein. Excessive ROS causes lipid peroxidation, denature proteins and mutate DNA, and eventually leads to cell apoptosis.⁴³ Collectively, these results indicate that SAV-5 ameliorates the products of intracellular ROS and lipid peroxidation, and protects the fragile cell membrane against oxidative damage in H₂O₂-treated LO2 cells.

SAV-5 attenuated H₂O₂-induced loss of mitochondrial membrane potential

In mammalian cells mitochondria are the major source of ROS.⁴⁴ Mitochondrial membrane potential ($\Delta\Psi_m$) is fundamental to the maintenance of mitochondrial physiological function.⁴⁵ Excessive ROS accumulation can induce mitochondrial damage and lead to a collapse of $\Delta\Psi_m$.⁴⁶ In this study, we used the sensitive fluorescent probe JC-1 to examine the $\Delta\Psi_m$ by fluorescent microscopy. As shown in Fig. 3A, exposure of hepatocytes to 200 μM H₂O₂ increased the amount of green fluorescence, signified by the shift in the fluorescence spectrum of JC-1 from an aggregated form with orange-red fluorescence to a monomeric form with green fluorescence. In contrast, pretreatment with vinegar decreased the green fluorescence signals compared to H₂O₂ treatment alone. The red/green

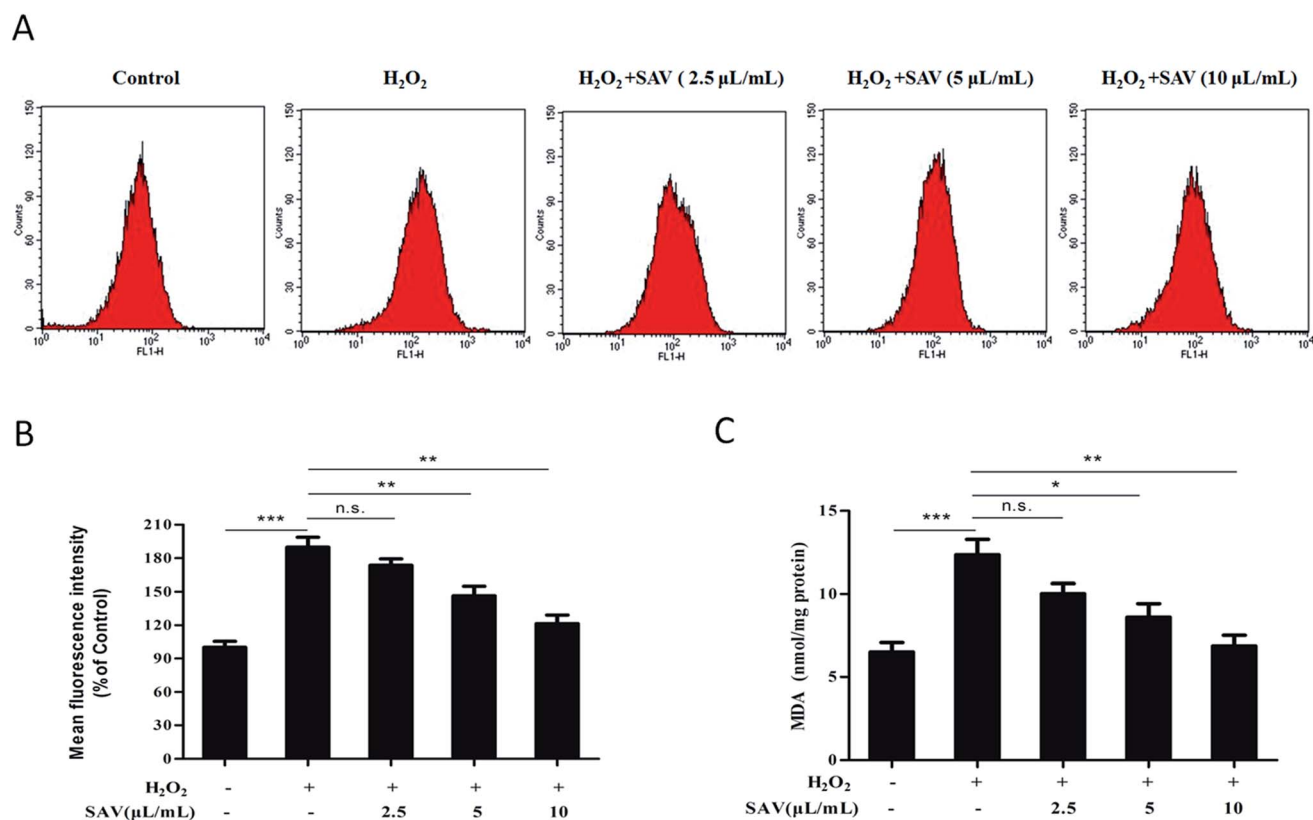

Fig. 2 SAV-5 reduced the levels of intracellular ROS and MDA in H₂O₂-treated LO2 cells. Cells were pretreated with various concentrations of vinegar for 24 h and then treated with 200 μM H₂O₂ for 6 h. (A) Cells were stained with DCFH-DA. The DCF fluorescence intensity was measured using flow cytometry. (B) The mean fluorescence intensity reflects intracellular ROS levels. (C) MDA level was measured with microplate reader. Data are presented as mean ± S.D. (*n* = 3) for each group. **p* < 0.05, ***p* < 0.01, ****p* < 0.001.

Fig. 3 SAV-5 attenuated H₂O₂-triggered loss of $\Delta\Psi_m$. Cells were treated with different ligands as previously described and stained with JC-1. (A) The fluorescence intensity was evaluated using fluorescent microscopy (bar = 10 μ M). (B) The ratio of red/green reflects mitochondrial membrane potential ($\Delta\Psi_m$). The corresponding histograms were quantified by Image J. All data are represented as mean \pm S.D. ($n = 3$) for each group. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

fluorescence intensity ratio indicates $\Delta\Psi_m$ levels. $\Delta\Psi_m$ depolarization is indicated by a decrease in the red/green fluorescence intensity ratio.⁴⁷ As shown in Fig. 3B, H₂O₂ treatment caused a dissipation of $\Delta\Psi_m$, whereas pretreatment with SAV-5 significantly attenuated the loss of $\Delta\Psi_m$ in a dose-dependent manner. These results indicate that SAV-5 can restore H₂O₂-triggered loss of $\Delta\Psi_m$ and stabilize mitochondrial function.

SAV-5 enhanced antioxidant enzymes activities and glutathione (GSH) level in H₂O₂-treated LO2 cells

Generally, exogenous H₂O₂ treatment can increase the levels of intracellular ROS and cause cellular oxidative damage.⁴⁸ Nevertheless, excessive ROS can be eliminated by hepatocyte antioxidant defense which induced by both enzymatic and

nonenzymatic mechanisms.^{49,50} In order to evaluate the effects of SAV-5 on antioxidant defense systems, SOD, CAT activities and GSH level were detected in H₂O₂-treated LO2 cells. SOD and CAT are two important antioxidant enzymes for preventing oxidative damage.⁵¹ GSH is a major tissue antioxidant, which is maintained in the reduced form by glutathione reductase and provides reducing equivalents for the glutathione peroxidase (GPx) catalyzed reduction.⁵² The results showed that SOD, CAT activities and GSH level in H₂O₂-treated group were markedly decreased compared with that in control group. However, pretreatment with SAV-5 increased the activities of SOD and CAT, although the effect of 2.5 μ L mL⁻¹ vinegar was not statistically significant (Fig. 4A and B). Consistent with antioxidant enzymes activities, GSH level was also significantly increased in H₂O₂-treated LO2 cells pretreated with SAV-5

Fig. 4 SAV-5 restored SOD, CAT activities and GSH level in H₂O₂-treated LO2 cells. Cells were treated with different ligands as previously described. SOD activity (A), CAT activity (B) and GSH level (C) were measured with microplate reader. Data are expressed as mean \pm S.D. ($n = 3$). * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

(Fig. 4C). Collectively, pretreatment with vinegar effectively restored SOD, CAT activities and GSH level in H₂O₂-treated LO2 cells. These data suggest that SAV-5 enhances the antioxidant status that can prevent oxidative damage in H₂O₂-treated LO2 cells.

SAV-5 up-regulated Nrf2-mediated antioxidant gene expression

To further clarify underlying antioxidant mechanisms of vinegar, the expression levels of Nrf2 and phase II detoxifying

enzyme were analyzed by western blotting. Nrf2 is the key transcription factor regulating an adaptive response to oxidative stress. When challenged by oxidative stress, Nrf2 can quickly translocate into the nucleus and elicit the antioxidant response.^{53,54} In the present study, the results showed that the expression level of Nrf2 was increased when LO2 cells were pretreated with vinegar (Fig. 5A). Then, the free Nrf2 is combined with an antioxidant response element (ARE) and activates important antioxidant proteins and phase II detoxifying enzymes, such as HO-1 and NQO1.⁵⁵ HO-1 is an inducible

Fig. 5 Effects of SAV-5 on expression of Nrf2 and downstream genes in H₂O₂-treated LO2 cells. Cells were treated with different ligands as previously described. (A) The expression levels of Nrf2-mediated antioxidant proteins were detected by western blot analysis. (B) Quantification of Nrf2 protein expression. (C) Quantification of NQO1 protein expression. (D) Quantification of HO-1 protein expression. Data are expressed as mean \pm S.D. ($n = 3$). * $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$, comparing to H₂O₂ group.

cytoprotective enzyme that can catalyze the rate-limiting step to degrade free heme into bilirubin, which could serve as an endogenous antioxidant.⁵⁶ NQO1 is a cytosolic flavoprotein that catalyzes the two electron reduction of quinoid compounds using NADH and/or NADPH as electron donors.⁵⁷ HO-1 and NQO1 genes are crucial mediators in maintaining antioxidant homeostasis during cellular stress.⁵⁸ As shown in Fig. 5B, after treatment with H₂O₂, the expression levels of HO-1 and NQO1 were decreased compared to the control group. However, pretreatment with SAV-5 prior to H₂O₂ exposure significantly increased the expression levels of these proteins. Collectively, the results demonstrated that SAV-5 up-regulated the expression of antioxidants and phase II detoxifying enzymes such as HO-1 and NQO1, which were regulated by Nrf2 signaling pathway. These findings suggest that the hepatoprotective effects of SAV against H₂O₂-induced oxidative damage in LO2 cells are mainly mediated by the activation of Nrf2 pathway.

Conclusions

In the present study, the antioxidant activities and hepatoprotective mechanisms of vinegar were assessed. SAV-5 was rich in phenolic and flavonoid compounds, and had the highest antioxidant activities among all the samples. Meanwhile, SAV-5 attenuated H₂O₂-induced cytotoxicity in human LO2 cells and exhibited protective effects by inhibiting intracellular ROS generation, restoring the loss of $\Delta\Psi_m$, and enhancing antioxidant defense systems under H₂O₂-induced oxidative damage. In addition, SAV-5 up-regulated the expression levels of Nrf2 and downstream genes (NQO1 and HO-1) in H₂O₂-treated LO2 cells. Collectively, the results suggest that SAV can protect human liver cells against H₂O₂-induced oxidative damage *via* antioxidant activity and Nrf2-mediated antioxidant responses.
