Higher UV-shielding ability and lower photocatalytic activity of TiO$_2$@SiO$_2$/APTES and its excellent performance in enhancing the photostability of poly(p-phenylene sulfide)

Yali Bai, Zhenhuan Li, Bowen Cheng, Maliang Zhang and Kunmei Su

U–TiO$_2$ is successfully coated with SiO$_2$ and subsequently well modified by APTES, and the core–shell structure exists on TiO$_2$@SiO$_2$ and TiO$_2$@SiO$_2$/APTES, which greatly reduces aggregation of the TiO$_2$ nanoparticles. The photocatalytic activities of U–TiO$_2$, TiO$_2$@SiO$_2$, and TiO$_2$@SiO$_2$/APTES are evaluated using MB decomposition. Nearly 50% of the MB is degraded after 15 min in the presence of the U–TiO$_2$ under UV radiation (300 W), and only 17.44% and 4.18% of the MB is degraded in the presence of the TiO$_2$@SiO$_2$-0.6 and TiO$_2$@SiO$_2$/APTES-1. However, TiO$_2$@SiO$_2$/APTES-0.6 and TiO$_2$@SiO$_2$-0.2 exhibit excellent UV absorbance capacities, and the TiO$_2$@SiO$_2$/APTES-0.6 achieves 80% of the UV-shielding ability of U–TiO$_2$. Poly(p-phenylene sulfide) (PPS) is an easily photodegraded material and TiO$_2$/PPS is more seriously photodegraded than PPS, however, the TiO$_2$@SiO$_2$/APTES nanoparticles can effectively protect the PPS from UV degradation, owing to their lower photocatalytic activities, higher UV-shielding abilities and easy dispersion in the PPS matrix. The breaking strength retention rate of the 1 wt% TiO$_2$@SiO$_2$/APTES/PPS film shows a maximum increase of 38.26%, and the breaking elongation retention rate increased by 41.64% at 2 wt% TiO$_2$@SiO$_2$/APTES loading. These results reveal that the incorporation of the TiO$_2$@SiO$_2$/APTES nanoparticles into the PPS matrix imparts excellent anti-UV properties to the PPS matrix, leading to a mechanical performance improvement.

Introduction

Over the last few years, increasing reports of ultraviolet aging owing to the collapse of the ozone layer have made people greatly aware of the danger to polymers from prolonged exposure to UV rays. The ultraviolet degradation of polymers is hugely important because resistance to aging, especially to UV light, is a key factor for outdoor applications. UV light, which accounts for about 7% of terrestrial sunlight, has been proven to cause aging of polymers, such as yellowing, brittleness, and even degradation. Both organic ultraviolet light stabilizers and inorganic nanoparticles have been introduced into polymer matrices to improve the UV stability of polymers. Compared with organic UV filters, inorganic nanoparticles are generally accepted as more stable and safe anti-UV agents. In particular, as an inorganic anti-UV agent, rutile TiO$_2$ nanoparticles have been widely employed in polymers to shield against UV radiation.

It is well known that TiO$_2$ has excellent photocatalytic activity. However, for sunscreen and other applications that require a low photocatalytic activity, it would be of great value to modify the performance of TiO$_2$. TiO$_2$ nanoparticles absorb UV light and catalyze the formation of super oxide and hydroxyl radicals on the surface of the TiO$_2$, and then these radicals may cause the degradation of organic components. Therefore, TiO$_2$ is generally coated with inert materials such as SiO$_2$ and Al$_2$O$_3$ to inhibit its photocatalytic activity by disturbing the formation of these radicals, which are produced by the reaction of O$_2$ and/or H$_2$O with the electron–hole pair. Using a microwave assisted sol–gel method, Furusawa et al. coated rutile TiO$_2$ with SiO$_2$ to suppress its photocatalytic activity. Similarly, Siddiquay et al. applied a MW irradiation method to obtain the SiO$_2$ coated TiO$_2$ nanoparticles, which showed a higher inhibition of photocatalytic activity and superior UV-shielding characteristics than those of particles coated using the conventional solution method. In a report by El-Toni et al., control of the SiO$_2$ shell thickness and microporosity of TiO$_2$–SiO$_2$ core–shell type nanoparticles was conducted to depress the photocatalytic activity of TiO$_2$. The coating parameters were optimized to attain larger amounts of precipitated SiO$_2$ and thicker shells with lower microporosity, which in turn resulted in great depression of the photocatalytic activity. In previous research, treatments of the TiO$_2$ surface with various silane coupling agents were also conducted. Zhao et al. have applied 3-
aminopropyltrimethoxysilane (APTMS) and 3-isocyanatopropyltrimethoxysilane (IPTMS) to coat commercial TiO2 nanoparticles, which acted to suppress the photocatalytic activity of the TiO2 nanoparticles while maintaining their excellent UV-shielding properties. However, the UV-shielding ability of the original TiO2 particles decreases as a result of excessive coating. Thus, the effective inhibition of the photocatalytic activity with lower coating amounts will be essential for anti-photaging in organic polymers. So, it can be speculated that simultaneous or continuous coating of SiO2 and a silane coupling agent is potentially useful for suppressing the photocatalytic activity and maintaining the excellent UV-shielding ability by changing the surface characteristics.20

PPS is a semicrystalline engineering plastic with a symmetrical rigid backbone chain composed of para-substituted phenylene rings and sulfur atoms. It possesses excellent properties such as heat resistance, flame resistance, and corrosion resistance, which have resulted in PPS being widely applied in electronics, aerospace, and chemical industries, etc.21 However, due to the poor UV-resistance properties, the photodegradation of PPS manifests itself not only in yellowing and color darkening, but also in a serious reduction of the mechanical properties as a result of UV radiation.22,23 The last one is the most important obstacle to the practical application of PPS. To the best of our knowledge, few studies regarding the preparation of anti-UV PPS materials have been published.22

In this manuscript, TiO2 nanoparticles coated with different thicknesses of SiO2 were prepared from tetraethoxysilane (TEOS) and commercial TiO2 nanoparticles, and TiO2@SiO2 was further modified with APTES. The photocatalytic activities and UV-shielding capabilities of TiO2@SiO2 and TiO2@SiO2/APTES were characterized, and the nanoparticles with optimal performance were selected to improve the UV-resistance properties of PPS. The photo stability of the PPS composite under UV-radiation was studied using an ultraviolet accelerated weatherometer, and the aim of this work is to suppress the photocatalytic activity of TiO2 and improve its dispersion in PPS to develop a stable and safe inorganic sunscreen with superior UV-shielding capability and inhibited photocatalytic activity.

Experimental section

Materials

The PPS resins (0320) used in this study were purchased from Ticona Engineering Polymers Co, in powder form. Rutile TiO2 nanoparticles and 3-aminopropyltriethoxysilane (APTES) were provided by Aladdin Industrial Corporation. Tetraethyl orthosilicate (TEOS) was supplied by Aldrich-Sigma. Methylene blue (MB) was obtained from Kermel Chemical Reagent Co. Ltd (Tianjin, China). These reagents were used as received without further purification.

Synthesis of the SiO2 coated TiO2 nanoparticles

0.5 g of TiO2 nanoparticles were homogeneously dispersed in a mixed solution of ethanol (140 mL), deionised water (30 mL), and ammonia aqueous solution (28%, 3.0 mL), and then the TiO2 nanopowder dispersion was subjected to mechanical stirring and sonication in a water bath. Subsequently, the appropriate amount (TEOS/TiO2 weight ratio = 0.2, 0.4, 0.6) of TEOS pre-dissolved in ethanol (10 mL) was added to the above mixture. After 2 h, the sonication was stopped and the mixture was kept stirring for 6 h. Then, the SiO2 coated TiO2 nanoparticles were separated from solution by centrifugation (8000 rpm, 10 min) followed by washing with ethanol several times. After the process was finished, the particles were dried in a vacuum oven at 60 °C for 12 h. The sample modified by TEOS was described as TiO2@SiO2 and the sample without treatment was described as U–TiO2.

APTES modification of the TiO2 and SiO2 coated TiO2 nanoparticles

A precise amount of TEOS (TEOS/TiO2 weight ratio = 0.2) was added to the TiO2 nanoparticle suspension. Subsequently, an appropriate amount (APTES/TiO2 weight ratio = 0.2, 0.6, 1) of APTES together with ethanol (10 mL) was loaded into the TiO2 nanoparticle suspension dropwise under continuous stirring and sonication conditions. After 2 h, the sonication was stopped and the mixture was kept stirring for 6 h. APTES modification of the SiO2 coated TiO2 nanoparticles was obtained by centrifugation (8000 rpm, 10 min) followed by washing with ethanol and deionised water alternately for at least 3 cycles, and drying for 12 h in a vacuum oven at 60 °C. The sample modified with APTES was described as TiO2@SiO2/APTES.

Preparation of the PPS composite films

The PPS composite films were prepared by mixing nanoparticles into the PPS matrix, using caprolactam as the solvent, at 255 °C. Subsequently, the obtained mixture was quickly poured onto the surface of a hot plate and spread with a casting bar into thin films. And then the PPS composite films were placed into the alcohol and water bath alternately for more than 24 hours to completely remove the solvents. Finally, the films were freeze-dried using a freeze dryer. Four composite films were prepared, with nanoparticle quantities of 0.5, 1.0, 2.0 and 5.0 wt%, respectively. For comparison, the neat PPS films were also prepared under the same conditions.

Photocatalytic activity measurement

The photocatalytic activities of the TiO2@SiO2 and TiO2@SiO2/APTES particles were characterized by measuring the decomposition of methylene blue (MB). The dried samples (0.1 g) were loaded into a MB aqueous solution (10 mg L\(^{-1}\), 200 mL) with the aid of sonication. The obtained suspension was kept in the dark and magnetically stirred for 1 h to ensure adsorption-desorption equilibrium of MB on the surface of the samples. Then the suspension was illuminated for 90 min in the photochemical reactors (UV lamp, 300 W) with continuous stirring and sampling at 15 min intervals from the reaction system. The absorbance of MB at 664 nm was measured using a UV-vis spectrophotometer (V-1200, MAPADA).
UV treatment of the PPS composite films
The neat PPS films and composite films were irradiated in the ultraviolet accelerated weatherometer (Dongguan, China) for 192 h. The distance between the films and the UV lamp (313 nm, 95 W) was fixed at 7 cm.

Characterization techniques
The morphology of the PPS composite films was characterized using a S-4800 Hitachi scanning electron microscope (SEM). TEM images were obtained from a H7650 Hitachi transmission electron microscope to examine the uniformity and dispersion of the nanoparticles. Infrared spectra were recorded on a TENSOR 37 Fourier transform infrared spectroscope (FT-IR, BRUKER, Germany) in the wavenumber range of 4000–400 cm\(^{-1}\). X-ray photoelectron spectroscopy (XPS) was performed on a Thermo Fisher K-alpha photoelectron spectrometer. The thermal behavior of the nanoparticles was evaluated using STA409 PC thermogravimetry (TG, NETZSCH, Germany) under a N\(_2\) atmosphere from room temperature to 1000 °C with a heating rate at 10 °C min\(^{-1}\). The contact angle of the nanoparticles was measured using a DSA 100 (KRUSS) drop shape analysis system. Before the measurement, adequate amounts of nanoparticles were dispersed in ethanol with ultrasonic treatment for 1 h. Then, the suspension was dropped onto the surface of a glass plate to form a uniform film. Every film was tested at least three times and then an average value was obtained. A UV-vis spectrophotometer (Lambda 750, PerkinElmer) was used to characterize the transmittance of the films with and without the modified nanoparticles. The mechanical properties of PPS films before and after UV radiation for 192 h were determined with a single strength tester (LLY-06, China) at ambient temperature. The lengths and widths of each film were 30 mm and 10 mm. Fifteen films of every sample were tested and the average values were evaluated.

Results and discussion

FT-IR studies of the nanoparticles
FT-IR spectra of the U–TiO\(_2\), TiO\(_2\)@SiO\(_2\) and TiO\(_2\)@SiO\(_2\)/APTES nanoparticles are shown in Fig. 1. All spectra (Fig. 1c and d) show that adsorbed water and hydroxyl groups existed on the surface of all of the samples, revealed by the presence of the broad peak at around 3420 cm\(^{-1}\) and the sharp peak at around 1630 cm\(^{-1}\). An intense absorption peak is also found at 800–400 cm\(^{-1}\), which was assigned to the stretching vibration of the Ti–O–Ti bond. For the TiO\(_2\)@SiO\(_2\) particles, new peaks at 1229, 1157, 1071 and 941 cm\(^{-1}\) are also observed. According to the literature, the characteristic peak at 1071 cm\(^{-1}\) is caused by the stretching vibration of the Si–O–Si bond. Furthermore, the absorption peaks at 1157 cm\(^{-1}\) and 941 cm\(^{-1}\) arise from Si–OH groups and the Ti–O–Si bond, respectively. The appearance

Fig. 1 FT-IR spectra of (a) U–TiO\(_2\), TiO\(_2\)@SiO\(_2\) (weight ratio = 0.2, 0.4, 0.6) and (b) U–TiO\(_2\), TiO\(_2\)@SiO\(_2\)/APTES (weight ratio = 0.2, 0.6, 1) at a range of 1700–400 cm\(^{-1}\), (c) U–TiO\(_2\), TiO\(_2\)@SiO\(_2\) (weight ratio = 0.2, 0.4, 0.6) and (d) U–TiO\(_2\), TiO\(_2\)@SiO\(_2\)/APTES (weight ratio = 0.2, 0.6, 1) at a range of 3600–1500 cm\(^{-1}\).
of these peaks clearly shows that the condensation reaction of Si(OH)₄ and the hydrolyzed production of TEOS and TiO₂ surface hydroxyl groups takes place to form Ti–O–Si bonds. In addition, the peak intensity of the Si–O–Si bond (1071 cm⁻¹) and the Ti–O–Si bond (941 cm⁻¹) increases with an increasing amount of the SiO₂ coating, suggesting that the SiO₂ shell tends to be denser when increasing the amount of SiO₂ coating. Similarly, for the TiO₂@SiO₂/APTES particles, the intensity of the absorption peaks at 1631 (Fig. 1d) and 1050 cm⁻¹ (Fig. 1b) increases with increasing APTES loading amounts. It can be considered that the peak of the N–H bending vibration of primary amine overlap with the peak (1631 cm⁻¹) arising from the H–O–H bending vibration. These analyses show that the TiO₂@SiO₂ nanoparticles are successfully prepared and modified with APTES.

XPS studies of the nanoparticles

XPS analysis was utilized to characterize the chemical composition of the nanoparticles’ surface. The survey spectrum in Fig. 2A shows the presence of C, O, and Ti in the U–TiO₂ and C, O, Ti, and Si in the TiO₂@SiO₂, while elements C, O, Ti, Si, and N are found in the TiO₂@SiO₂/APTES. The high-resolution detailed XPS spectra were carried out around peaks of interest, specifically C 1s, O 1s, Ti 2p, Si 2p, and N 1s. Fig. 2B shows high-resolution spectra of the C 1s signal of (a) U–TiO₂, (b) TiO₂@SiO₂, and (c) TiO₂@SiO₂/APTES. In the C 1s XPS line, three C components, C₁, C₂, and C₃, are fitted and assigned according to literature values. The binding energy of the C₁, C₂, and C₃ peaks for U–TiO₂ at 284.8, 285.4, and 288.7 eV is attributed to the presence of CH₃ and C–O and C=O bonds, respectively. Similarly, the C₁, C₂, and C₃ peaks of the TiO₂@SiO₂ nanoparticles at 284.9, 285.6, and 286.6 eV arise from CHₓ and C–O and C=O bonds, respectively. The above peaks (CHₓ, C=O and C=O bonds) come from hydrocarbon impurities typically obtained during sample preparation and transportation. The TiO₂@SiO₂/APTES also exhibits three carbon components at 284.9, 285.6, and 286.4 eV, which are assigned to CHₓ/C–C–Si, C–H/C–N and C=O functions, respectively.

The C₃ component is probably caused by the mixture of organic residues during sample treatment because the carbonyl function does not exist in APTES. The presence of C₃ in the U–TiO₂ indicates that APTES was successfully grafted on to the surface of the TiO₂ and followed modification with APTES. The presence of the C₁ 532.4 eV is also attributed to the surface of the TiO₂ and followed modification with APTES. The presence of sharp peaks at 103.9 eV in the Si 2p spectrum, the binding energy of the U–TiO₂ is at 459.3 eV, 0.4 eV greater than the Ti 2p peak (103.9 eV) for Si, and N 1s. In the Ti 2p3/2 Spectrum, the binding energy of the U–TiO₂ is found at 458.9 eV, whereas that of the TiO₂@SiO₂ is at 459.3 eV, 0.4 eV greater than the Ti 2p3/2 peak of U–TiO₂. These results also clearly confirm the Ti–O–Si bond formation. The decrease of the electron density around the Ti atom is caused by the greater electronegativity of Si via O acting on Ti. The shielding effect is weakened, so the binding energy of the TiO₂@SiO₂ increased. However, the Ti 2p peak position of the TiO₂@SiO₂/APTES has no obvious chemical shift compared with the U–TiO₂. It can be attributed to the fact that APTES mainly reacts with the Si–OH groups, and thus it has almost no influence on the binding energy of the Ti 2p of the U–TiO₂. Furthermore, the intensity of the Ti 2p peak significantly decreases after SiO₂-coating and APTES modification, suggesting that the SiO₂-coating actually formed on the surface of the TiO₂ and followed modification with APTES. The presence of sharp peaks at 103.9 eV in the Si 2p signal in agreement with the Si 2p in SiO₂, which also indicates that the surface of the TiO₂ is coated with SiO₂. After the TiO₂@SiO₂ is treated with APTES, the binding energy of Si 2p shifts negatively by 0.7 eV. This negative shift indicates that APTES has been grafted onto the TiO₂@SiO₂ surface. The presence of three new peaks at 399.8, 401.1, and 402.2 eV in the N 1s spectrum provides direct evidence of the successful
grafting of APTES onto the surface of the TiO₂@SiO₂. The peak at 399.8 eV is attributed to the terminal amine groups on the APTES, whereas the peaks at 401.1 and 402.2 eV probably resulted from protonated amine NH₃⁺ or hydrogen bonded NH₂. Previous reports have shown that APTES has different attachment modes. The Si end of the APTES can react with the silanol groups of the TiO₂@SiO₂ via a condensation reaction to form Si–O–Si bonds, and the free NH₂ termination can be observed at 399.8 eV (the desired attachment). However, if the NH₂ groups of the APTES are attached to the surface (reverse attachment) through ionic bonding or hydrogen bonding with the silanol groups of the TiO₂@SiO₂, protonated amine NH₃⁺ or hydrogen bonded NH₂ can be observed at 401.1 or 402.2 eV, respectively. The reverse attachment of the APTES reveals that the silanization process is accompanied by a secondary reaction, which is in agreement with literature reports. The thermogravimetric (TG) curves of the U–TiO₂, TiO₂@SiO₂, and TiO₂@SiO₂/APTES are shown in Fig. 3. As can be seen from the curves, the U–TiO₂ is relatively stable and only slightly decomposed. The weight loss at the initial stage between 95 °C and 200 °C is probably due to the loss of water physically adsorbed on the surface of the nanoparticles. From 340 °C to 420 °C, the weight loss of the U–TiO₂ is mainly attributed to the reduction of OH on its surface. The weight loss of the TiO₂@SiO₂ is 2.47% between 300 °C and 670 °C, which is attributed to the reduction of OH on its surface and the decomposition of the residual organic group (–CH₂CH₂) of the TEOS. A significant decrease in weight, with 3.82% weight loss, can be observed from the curve of the TiO₂@SiO₂/APTES at 300–670 °C, which is mainly caused by thermal decomposition of the APTES. The TG analysis thus reconfirms that the TiO₂ is successfully coated with SiO₂ and subsequently modified by APTES.

**Contact angle analysis**

Contact angle tests are carried out to evaluate the hydrophobicity of the U–TiO₂, TiO₂@SiO₂, and TiO₂@SiO₂/APTES. The contact angle of the TiO₂@SiO₂ approximately reaches 0°, indicating that the TiO₂@SiO₂ is superhydrophilic. As shown in Fig. 4, the contact angle of the TiO₂@SiO₂/APTES obviously increases from 18.1 to 54.9° because of some hydrophobicity of the organic APTES, which could improve the compatibility of TiO₂ with organics or polymers.

**TEM analysis**

TEM images of the U–TiO₂, TiO₂@SiO₂, and TiO₂@SiO₂/APTES are shown in Fig. 5. It is clearly observed that the U–TiO₂ nanoparticles are seriously aggregated and distinct particles can be hardly found. However, the TiO₂@SiO₂ (Fig. 5b) and TiO₂@SiO₂/APTES (Fig. 5c) nanoparticles are evenly or well distributed, without forming agglomerates. It can be seen that the homogeneous SiO₂ coating was deposited on the surface of the TiO₂ and formed a continuous coating layer (Fig. 5e). Similarly, APTES was also predominately deposited on the TiO₂@SiO₂ nanoparticles’ surface and an obvious interface can be detected (Fig. 5f). The core–shell structure existed when the TiO₂ nanoparticles were modified with TEOS and APTES. After being coated by SiO₂ and further modified with APTES, the aggregation of the TiO₂ nanoparticles is greatly reduced.

**Photocatalytic activities of the nanoparticles**

The photocatalytic activities of the U–TiO₂, TiO₂@SiO₂, and TiO₂@SiO₂/APTES are evaluated by measuring MB decomposition. With increasing SiO₂ coating and APTES loading amounts, the MB degradation rate decreased remarkably (as shown in Fig. 6). The available data indicate that the photocatalytic activity of TiO₂ is suppressed effectively after SiO₂ coating and
APTES modification because the direct contact between the MB molecule and the surface of the TiO₂ nanoparticles is interfered with by the SiO₂ coating and APTES deposited on the TiO₂ surface. Nearly 50% of the MB is degraded after 15 min in the presence of the U–TiO₂ nanoparticles under strong UV radiation (300 W), while only 17.44% and 4.18% of the MB is degraded in the presence of the TiO₂@SiO₂-0.6 and TiO₂@SiO₂/APTES nanoparticles. The TiO₂ nanoparticles catalyze the formation of super oxides and hydroxyl radicals under UV light conditions, and these radicals may cause the degradation of organic components. After the TiO₂ is coated with SiO₂ and APTES, the photocatalytic activities of the TiO₂@SiO₂ and TiO₂@SiO₂/APTES were decreased through the inhibition of free radical production from the reaction of O₂ and/or H₂O with the electron–hole pair. Therefore, the TiO₂ surface was coated with SiO₂, and the prepared TiO₂@SiO₂ was further modified with APTES, which can effectively inhibit the photocatalytic activity of TiO₂. UV-shielding ability of the nanoparticles

To investigate the UV-shielding ability of the prepared nanoparticles, UV absorption of the nanoparticles is measured in a highly dilute suspension with a volume of 10 mg L⁻¹, which is shown in Fig. 7. The UV absorption at wavelengths ranging from 280–400 nm decreases gradually with the increase of the SiO₂ coating, indicating that excessive SiO₂ coating can remarkably restrain the UV-shielding ability of the TiO₂ nanoparticle (Fig. 7a). In comparison with the U–TiO₂, the UV absorption of the TiO₂@SiO₂/APTES decreases, but the UV absorption of the TiO₂@SiO₂/APTES-0.6 reaches the maximum value (Fig. 7b). As shown in Fig. 7c, the UV absorption capacity of the TiO₂@SiO₂/APTES-0.6 is higher than that of the TiO₂@SiO₂-0.2. These results suggest that the TiO₂ coated with SiO₂ and further modified by appropriate amounts of APTES can more effectively maintain the UV-shielding ability than the TiO₂@SiO₂. Although the UV-shielding ability of the TiO₂@SiO₂/APTES-0.6 nanoparticles is also reduced in comparison with the U–TiO₂, it can remain above 80%. Based on these results, it is found that the TiO₂@SiO₂/APTES-0.6 nanoparticles can more effectively quench the photocatalytic activities and retain high UV-shielding ability. So the TiO₂@SiO₂/APTES-0.6 is the best candidate to improve the anti-UV properties of polymers.

FT-IR studies of the PPS composite films

Fig. 8 presents the ATR-FTIR spectra of the PPS film before and after UV irradiation for 192 h, in order to obtain information about the photoaging degradation of PPS. The spectrum of the neat PPS film exhibits absorption peaks at 1573, 1470, 1388, 1092, 1008, and 807 cm⁻¹. The characteristic peaks at 1573, 1470, and 1388 cm⁻¹ are assigned to the skeleton stretching vibration of the aromatic rings. The absorption peak at 1092 cm⁻¹ is related to stretching of the C=S bond. In addition, the peaks at 1008 and 807 cm⁻¹ are assigned to the in-plane C–H bending and the out-of-plane deformation vibration of ≡C–H, respectively. After UV irradiation for 192 h, the intensity of the above PPS characteristic absorption peaks decreased obviously, but some new absorption peaks were detected at 3206, 3053, 1716, 1320, 1159, 1035, 647, and 619 cm⁻¹, which confirmed that photodegradation of PPS can be induced by UV rays. The new broad peaks at 3206 and 3053 cm⁻¹ are assigned to phenolic groups, which indicates that the oxidation reaction takes place at the aromatic rings of PPS. Furthermore, the characteristic absorption at 1716 cm⁻¹ is attributed to the skeletal stretching vibration of the 1,2,4-trisubstituted phenyl...
ring, which results from the formation of crosslinking groups after cleavage of the PPS chain. The intensity of the peak at 1180 cm\(^{-1}\) related to crystalline components decreased, which results from the poor regularity of the PPS chain. The PPS chain cleavage caused by UV radiation can reduce its crystallization degree, which increases the amount of amorphous components. Moreover, the absorption peak intensity of the C–S bond also decreased after UV irradiation for 192 h. The new characteristic absorption peaks at 1320, 1159, and 1035 cm\(^{-1}\) are attributed to the –SOO' stretching and –SO' stretching vibrations. These results confirm the fact that the C–S bond can be cleaved under UV irradiation. The absorption peaks that occurred at 647 and 619 cm\(^{-1}\) are attributed to small molecules' or oligomers' stretching vibrations. The above results indicated that the PPS films were photodegraded seriously under UV rays due to their poor anti-UV properties.

Fig. 9 presents the ATR spectra and cross-sectional SEM images of the TiO\(_2\)/PPS film in comparison with the TiO\(_2\)@SiO\(_2\)/APTES/PPS film. As shown in Fig. 9a, the TiO\(_2\)/PPS film is photodegraded seriously, which is consistent with the process of neat PPS photodegradation. However, the ATR spectrum of the TiO\(_2\)@SiO\(_2\)/APTES/PPS film has nearly no changes before and after UV irradiation for 192 h (Fig. 9b). U–TiO\(_2\) agglomerates are formed in the TiO\(_2\)/PPS film (Fig. 9c), however, TiO\(_2\)@SiO\(_2\)/APTES can be well dispersed in the PPS film (Fig. 9d). These results confirm the idea that the U–TiO\(_2\) degrades the PPS macromolecule chain due to its excellent photocatalytic activity and poor dispersion properties, while the TiO\(_2\)@SiO\(_2\)/APTES nanoparticles can effectively protect the PPS from UV ray degradation owing to their lower photocatalytic activity, higher UV-shielding ability and easy dispersion in the PPS matrix.

UV-screening properties of the TiO\(_2\)@SiO\(_2\)/APTES/PPS films

To investigate the UV-screening properties of the TiO\(_2\)@SiO\(_2\)/APTES/PPS films, UV transmittance is measured at a wavelength of 350–395 nm which belongs to the maximum absorption range of the TiO\(_2\)@SiO\(_2\)/APTES nanoparticles, as shown in Fig. 10. The UV transmittance of the PPS film is very low (<5%), which indicates that the PPS film has considerably strong UV absorption. The UV transmittance of the TiO\(_2\)@SiO\(_2\)/APTES films decreases with increasing nanoparticle loading amounts, which is consistent with the excellent UV-shielding ability of the TiO\(_2\)@SiO\(_2\)/APTES nanoparticles. Thus, taking advantage of the absorbing and scattering of UV rays, the TiO\(_2\)@SiO\(_2\)/APTES nanoparticles can effectively protect the PPS matrix from UV radiation.

SEM analysis

In order to investigate the phenomenon of photoaging degradation, SEM images of the PPS films and TiO\(_2\)@SiO\(_2\)/APTES/PPS films were characterized before and after UV irradiation for 192 h. As shown in Fig. 11, it can be clearly seen that there are some obvious cracks and small holes on the surface of the PPS film, but no structure defects exist on the TiO\(_2\)@SiO\(_2\)/APTES/PPS film after UV irradiation for 192 h. These results demonstrate that the UV resistance of the PPS was significantly improved by the TiO\(_2\)@SiO\(_2\)/APTES nanoparticles, which is consistent with the ATR-FITR characterization results.

Color change analysis

From the photographs of the films (Fig. 12), it can be observed that UV radiation causes a dramatic change in the color of the
neat PPS film, resulting in a deep yellow color. However, the TiO$_2$@SiO$_2$/APTES/PPS composite film only exhibits minimal yellowing, which suggests that the TiO$_2$@SiO$_2$/APTES nanoparticles are effective in protecting the PPS from discoloration due to UV radiation.

**Mechanical properties of the films**

To further evaluate the effects of UV-resistance on the mechanical properties of PPS, tensile tests are carried out on films subjected to UV irradiation for 192 h at a tensile speed of 10 mm min$^{-1}$. Their breaking strength retention rates and breaking elongation retention rates are shown in Fig. 13. The pure PPS film exhibits 50.35% and 45.82% breaking strength retention rate and breaking elongation retention rate, significantly lower than those of the TiO$_2$@SiO$_2$/APTES/PPS films. The breaking strength retention rate improvements are found for our TiO$_2$@SiO$_2$/APTES/PPS films, and the retention rate of the 1 wt% TiO$_2$@SiO$_2$/APTES/PPS film shows a maximum improvement of 38.26% but this reduces at higher filler loadings due to nanoparticle agglomeration (Fig. 13a). Regarding the breaking elongation retention rate (Fig. 13b), a maximum improvement of 41.64% can be observed at a 2 wt% TiO$_2$@SiO$_2$/APTES loading, and this also shows a small decrease at higher loadings due to poor nanoparticle dispersion. These results reveal that the incorporation of the TiO$_2$@SiO$_2$/APTES nanoparticles into the PPS matrix imparts excellent anti-UV properties to the PPS matrix, leading to the mechanical performance improvement.

**Conclusions**

In summary, TiO$_2$@SiO$_2$ nanoparticles were prepared using a sol–gel method from TEOS and TiO$_2$, and further treated with APTES to obtain the TiO$_2$@SiO$_2$/APTES nanoparticles. FT-IR, XPS, TG and contact angle analyses confirmed that the SiO$_2$ shell could be well deposited on the surface of core TiO$_2$, and that APTES could be further successfully attached on to the TiO$_2$@SiO$_2$ surface. TEM images revealed that the core–shell structure was formed on the surface of the TiO$_2$ and the APTES modified nanoparticles could be well dispersed in a PPS matrix. The TiO$_2$@SiO$_2$/APTES-0.6 nanoparticles are the best candidates for improving the UV-resistance of a PPS polymer because...
of their higher UV-shielding ability, lower photocatalytic activity and better dispersion. The TiO$_2$@SiO$_2$/APTES-0.6 nanoparticles were used as fillers in a PPS matrix, and ATR-FTIR analysis, UV screening tests, SEM characterization, and color change and tensile tests were used to investigate the anti-UV properties of PPS and its composites. Compared to the pure PPS film after UV irradiation, excellent anti-UV properties of the TiO$_2$@SiO$_2$/APTES/PPS composite films are manifested in the superior photostability, good UV transmittance ability, minimal yellowing, and remarkably enhanced mechanical properties. On the basis of these results, it can be concluded that the TiO$_2$@SiO$_2$/APTES nanoparticles are an excellent filler in PPS to improve UV resistance.
