Systematic study of the crystallization process of CrAPO-5 using *in situ* high resolution X-ray diffraction

Pei Sheng,^{ab} Guofu Wang,^a Mei Dong,^{*a} Gang Chen,^{ab} Huanhuan Yang,^{ab} Weibin Fan,^{ib} Zhangfeng Qin^a and Jianguo Wang^a

Chromium substituted nano-porous aluminophosphate (CrAPO-5) was investigated to discuss the effect of Cr³⁺ ions on the crystallization kinetics and crystal structure parameters by *in situ* time-resolved high resolution X-ray powder diffraction (HRXRPD). Results showed that the introduction of Cr³⁺ into pure AlPO₄-5 influenced both the crystallization velocity and structural parameters of the resultant AFI. The presence of Cr³⁺ ions can severely retard the crystallization of AFI. The more Cr³⁺ ions in the gels, the stronger inhibitory effect would be. A kinetic analysis of the crystallization of CrAPO-5 was performed. A fair linear relationship between the activation energy and Cr³⁺ content was concluded. The calculated Avrami exponent *n* was in the range of 1–1.4, implying a similar 1D growth mechanism to that of AlPO₄-5. The extracted structural parameters showed obvious crystal expansion, which might be caused by the trapping of Cr³⁺ ions in the framework. However, this influence on the structural parameters was limited. The *a* (= *b*) parameters increased to a maximum with chromium content, which is similar to the influence on the crystal growing velocity. The grain size variation of AFI differed from other metal substituted aluminophosphate molecular sieves, which implied a different state of chromium in the AlPO₄-5 framework. The time-resolved HRXRPD proves to be a direct and efficient method to reveal the influence of Cr³⁺ ions on the crystallization and shows indirect evidence on the state of Cr³⁺ in the crystallized CrAPO-5.

1. Introduction

Aluminophosphates have a crystalline three-dimensional network, in which aluminum and phosphorus tetrahedra are linked *via* oxygen atoms. The porous structure of molecular sieves, combined with their chemical composition, makes them uniquely suitable for use as catalysts or support materials. Isomorphous substitution of transition metal ions is an efficient technology to control cation-exchange capacity and acidity of the molecular sieve materials, which is a key parameter to determine the catalytic activity.^{1,2} Substitution for Al³⁺ has been claimed for a variety of metals,^{3–8} such as Mn(II), Co(II), Fe(II), Mg(II), Zn(II), which has attracted worldwide attention in the area of molecular sieve science and shape selective catalysis. It is worth mentioning that the pristine catalytic properties of chromium in redox reactions has evoked high interest in chromium containing molecular sieves over the past few years. Substitution of Al with Cr(III) in aluminophosphate molecular sieves (AlPO₄-5) does not induce additional framework charge

or ion-exchange ability as the parent framework is neutral. However, if the product exhibits a compositional heterogeneity with evenly distributed chromium centers, it influences the sorption properties of the material in a similar way as charged centers in other metal substituted AlPO₄-5. These sorption centers are able to interact with molecules adsorbed in the pores and act as a catalyst for reactions such as the oxidation of secondary alcohols and hydrocarbons in the liquid phase.^{9–13} Therefore, it is highly important to understand the crystallization mechanisms taking place during hydrothermal synthesis of aluminophosphate molecular sieves and metal-substituted ones, which will shed light on rational design and synthesis of new molecular sieves with specific crystalline structure, morphology and particle size for catalytic applications.

One problem generally overlooked in developing new catalytic system is the stability and heterogeneity of these materials under working conditions. Cr³⁺ in inorganic compounds exhibits a strong tendency to adapt octahedral coordination due to existence of stable trivalent ion and its 3d³ ground state which splits into three stabilizing and two destabilizing orbitals in an octahedral field. Substitution for Al³⁺ is consequently a difficult task as it requires tetrahedral coordination of chromium. On the other hand, the present methods used to investigate state of Cr ions heavily rely on ultraviolet/visible spectroscopy (UV-vis),^{14–16}

Raman spectroscopy,¹⁷ electron paramagnetic resonance (EPR),^{15,18–24} X-ray absorption spectroscopy (XAS)^{25–27} and nuclear magnetic resonance (NMR),²⁸ which all focused on the synthesized products. A large number of studies have been devoted to studying the transformation of gel to nanoporous materials using a variety of *in situ* techniques, like X-ray diffraction (XRD) methods,^{29–35} small-angle X-ray scattering (SAXS) techniques⁵ and X-ray absorption spectroscopy (XAS).^{36,37} Although a combined technique approach using all these methods has been reported to derive mechanistic aspects of the crystallization process,^{5,37} recent developments, particularly in the area of angular-dispersive high resolution powder X-ray powder diffraction (HRXRPD), make it possible to collect high-quality diffraction data in a very short time scale, which will not only determine the kinetics, but also the precise structural parameters, in particular the variation in lattice parameters of the reacting system. The *in situ* methods had been widely used on Co, Zn and Mn substituted aluminophosphate molecular sieves.^{5,32–34,36–41} However, there is no report so far on the *in situ* study of the crystallization process of CrAPO-5. We present here an *in situ* study of the hydrothermal crystallization of CrAPO-5 starting from the precursor gel prepared with the classical method to the crystalline material using the high resolution synchrotron powder X-ray diffraction (HRXRD). This approach allowed us to achieve a deep understanding of the influence of Cr ions on the crystallization process of CrAPO-5, to study the kinetics, to extract the structural parameters and to investigate the state of Cr ions in AlPO₄-5 frameworks during the synthesis process.

2. Experimental methods

2.1 Sample preparation

The AlPOs gels were prepared by a traditional method reported elsewhere.⁷ About 80–100 mL of each gel was prepared, sufficiently large for all synthesis and diffraction experiments performed. The following procedure was applied in the preparation of the gels: H₃PO₄ was first dissolved in water, followed by the addition of the transition metal ion salts. Then pseudo-boehmite was added to the solution under vigorously stirring after the transition metal salts were fully dissolved. Finally, after stirring for at least 60 min, triethylamine as templating molecule was introduced into the above mixture drop by drop under vigorous stirring. This mixture was further stirred for at least 2 h. The charges were stored at room temperature in polyethylene vials. The APO-gel was prepared with a similar procedure. Preliminary crystallization experiments were conducted at

200 °C in Teflon-lined autoclaves, and the obtained crystalline reaction products were identified from their X-ray powder patterns.⁴² The elemental composition analyzed by ICP were listed in Table 1.

No chemical analysis of the reaction products were performed, but a general composition can be given as

where *m* refers to the molar ratio of Cr to P. The obtained samples and gels were termed as CrAPO-5(*m*).

2.2 In situ measurements

A homemade device as shown in our previous work⁴³ was designed to meet the demands of *in situ* XRD analysis. In the *in situ* experiments, two heating modes were used: (i) heating of the gels from *ca.* 28 to 200 °C in 90 min at a constant heating rate (temperature ramp) and (ii) heating of the gels in 1 min from *ca.* 28 °C to a temperature between 140 and 170 °C and keeping the temperature for a certain period of time (isothermal). The *in situ* set-up and its detailed operation were described in our early work.⁴³ Four kind of gels with different Cr³⁺ content were studied using synchrotron radiation, as shown in Table 1.

The *in situ* XRD experiment was performed on the 4B9A beamline of BSRF at a fixed wavelength of 1.54 Å with MYTHEN as the detector. The superiority of the MYTHEN detector used in the powder diffraction had been summarized and verified in some studies.^{44–46} The detailed information about the MYTHEN detector in BSRF was described by Du.⁴⁵ Considering the signal-to-noise ratio of the spectra and the reaction speed, the duration of each data collection was optimized to 60 to 120 seconds to cover a 2-theta range of 120°. In fact, only the data in the range of 5 to 40 degrees was effective to extract the useful information. The data was processed using Jade 6.5 software to extract the lattice parameter of the crystallizing system as a function of time. The kinetic information was extracted using the Avrami equation. The structural parameters were calculated using the Debye–Scherrer equation.

3. Results and discussion

3.1 In situ XRD

3.1.1 Temperature ramp. Systems of AlPO₄-5 and CrAPO-5(*m*) (*m* = 0.01, 0.05, 0.08) were studied under temperature programmed condition. None of the four investigated gels

Table 1 Chemical composition of the as-synthesized samples and the corresponding gels

Sample	Cr ³⁺ content in the gels (wt%)	Cr content in the as-synthesized samples (wt%)	Element content in crystals (mol)			$\frac{n(\text{Cr} + \text{Al})}{n(\text{P})}$	$\frac{n(\text{P} - \text{Al})}{n(\text{P})}$
			Cr	Al	P		
AlPO ₄ -5	0	0	—	—	—	—	—
CrAPO-5(0.01)	0.09	0.24	0.006	0.992	1.00	1.00	0.008
CrAPO-5(0.05)	0.44	0.66	0.016	0.981	1.00	1.00	0.019
CrAPO-5(0.08)	0.70	0.82	0.020	0.983	1.00	1.00	0.017

showed formation of crystalline precursor phases before the formation of the [AFI] type crystalline products. It is clear from the stacked plots that only pure AFI phase is formed in the experiments, irrespective of the metal content. Fig. 1a and b displayed the powder patterns obtained during the *in situ* experiments when the gel $\text{AlPO}_4\text{-5}$ and CrAPO-5(0.05) was heated from 28 to 200 °C. The peak intensity fluctuation can be ascribed to the instability of the input beam intensity and the intensity of the peaks were not normalized. The crystallization of the AlPO_4 -gel starts at approximately 145 °C, while the gel of CrAPO-5(0.05) starts at approximately 150 °C. The temperature is close to that of MnAPO-5 ,³⁹ but is lower than that of CoAPO-5 .⁵ That means the introduction of Cr^{3+} ions into the $\text{AlPO}_4\text{-5}$ gels slowed down the crystallization process, and the degree was different for various metal content. With the same range of y axis, height of the first diffraction peak decreased with the addition of metal content, which implied that the crystallinity of the $\text{AlPO}_4\text{-5}$ was reduced when Cr^{3+} ions were introduced into the system. The phenomenon is consistent with other metal substituted aluminophosphates. Fig. 1c and d showed the patterns of the integral areas of different peaks vs. the crystallization time. It is obviously that the growth rate of (100) and (102/211) plane was higher than that of (210) and (002) plane, no matter whether there was metal ion in the gel or not. So CrAPO-5(m) could remain similar hexagonal prisms as that of $\text{AlPO}_4\text{-5}$.

3.1.2 Isothermal experiments: analysis of crystallization kinetics. In all isothermal experiments, the sample was heated quickly (within 1 min) to the desired temperature and kept at that temperature for certain period.

Fig. 2 showed the powder patterns of the CrAPO-5 gels with different Cr^{3+} content at 150 °C. The Bragg reflections appeared as soon as the gel was introduced into the cells when the molar ratio of Cr/P was 0.01. The time before the appearance of the Bragg reflections, named induction or nucleation time, became longer and longer with the increasing of the Cr^{3+} ions content in the gels. The nucleation time t_0 , to a certain extent, could present the apparent activation energy for the nucleation process.³² With the content of Cr^{3+} increasing, the nucleation time t_0 at 150 °C was prolonged, which indicates the increase of the apparent activation energy for the nucleation process.

Kinetic information on the isothermal crystallization process can be derived from the Avrami–Erofe'ev^{47–49} expression that is widely used to model phase transitions and crystal growth in solid-state chemistry using the extent of the reaction, α , to time t using the relationship

$$\alpha = 1 - \exp[-(k(t - t_0))^n] \quad (1)$$

where t_0 is the induction time, k is the rate constant, and n is the Avrami exponent. The exponent n can be used in most cases to deduce information about the rate of nucleation and the mechanism of nuclei growth.³⁹ Common values of n ranges

Fig. 2 Stack of powder XRD patterns obtained with CrAPO-5(*m*) when kept at 150 °C for the duration of the data collection: (a) AlPO₄-5; (b) CrAPO-5(0.01); (c) CrAPO-5(0.05); (d) CrAPO-5(0.08).

from 0.5 to 4 and contain information both on the dimensionality and the process of crystallization.⁵ Previous work has demonstrated the relevance of this equation in modeling a variety of solid-state reactions but showed that this expression is found to be most applicable in the range $0.15 < \alpha < 0.8$.^{50,51} During the crystallization, a Sharp–Hancock plot ($\ln(-\ln(1 - \alpha))$ vs. $\ln(t)$) has been used to obtain the gradient n and intercept $n \ln k$.^{52,53}

The crystallization curves for the isothermal *in situ* synthesis of Cr³⁺-substituted aluminophosphates were analyzed in order to extract kinetic information. The evolution of diffraction peak intensity as a function of time can be used to derive valuable information on the kinetics and mechanism involved in the crystallization process. The intensity can be determined by fitting one or several Bragg peaks with a Gaussian function and measuring the corresponding areas that are then converted to the extent of reaction (α), scaled from 0 to 1, using the relationship $\alpha(t) = I_{hkl}(t)/I_{hkl}(\max)$, where $I_{hkl}(t)$ is the integral area of the given peaks at time t and $I_{hkl}(\max)$ is the maximum integral area of these peaks. The sum of four Bragg reflections of 100,

210, 002 and 102/211 contributes to each of the peak intensity.

The crystallization curves of CrAPO-5 with different Cr ion content were given in Fig. 3a, while the plot of the evolution of the (100) Bragg reflection at half-maximum (FWHM) as a function of temperature was shown in Fig. 3b. The Sharp–Hancock plot has been used to obtain the parameters n and k . The obtained plots of the crystallization of AlPO₄-5 and CrAPO-5(*m*) at 150 °C presented in Fig. 4a are clearly linear over the whole extent of the data, confirming the validity of the model (outliers due to the occurrence of macroscopic inhomogeneity in the sample during the synthesis were not included in the linear fitting process). The calculated n and k were summarized in Table 2.

When the ratio of Cr/P was less than or equal to 0.05 in the gel, the resulting crystallization curves were typical for a crystallization process in aqueous system consisting of an initial period of induction (or nucleation) followed by rapid crystallization of the material and gradual growth of the crystallites until a constant value is reached, which implied the completion

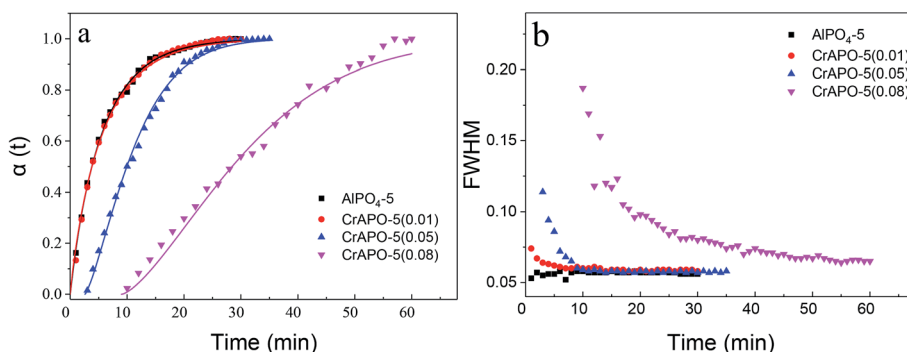

Fig. 3 (a) Crystallization curves extracted from isothermal *in situ* powder diffraction experiments at 150 °C. Solid curves are the fits to the Avrami expression, eqn (1); (b) the evolution of the experimental full-width at half-maximum (FWHM) of the Bragg reflection of (100).

Fig. 4 (a) Sharp–Hancock plots for the formation of $\text{AlPO}_4\text{-5}$ and $\text{CrAPO-5}(m)$ plotted data with the range from 0.15 to 0.8; (b) the plot of the rate constant k versus the Cr content in the gel at 150°C .

of crystal growth. The results are similar to that of Me^{2+} -substituted microporous aluminophosphates in aqueous system.^{32,34,36,38,41} The fitting curves using the n , k parameters calculated from the Sharp–Hancock plots showed highly consistent with the experimental crystallization curves. The Avrami exponent n of CrAPO-5 obtained from the Sharp–Hancock plots was larger than that of $\text{AlPO}_4\text{-5}$, and the rate constant k was smaller than that of $\text{AlPO}_4\text{-5}$, as shown in Table 2. These results illustrate that the nuclei growth and crystallization were both retarded in the presence of Cr ions. And the inhibitory effect became stronger and stronger with the increase of metal content in the gel. When the mole ratio of Cr/P was 0.01, the crystallization curve was almost overlapped by that of $\text{AlPO}_4\text{-5}$. The obtained n for different Cr^{3+} content was in the range of 1.0 to 1.3, which showed little variation with Cr^{3+} content. We conclude that the growth mechanism of CrAPO-5 with different Cr^{3+} content was similar to that of $\text{AlPO}_4\text{-5}$ and was independent with the Cr content within the studied range.

The FWHM, as manifested in Fig. 3b, was used to determine the variation in crystallite size with Cr^{3+} content. The FWHM values for all systems decreases sharply with the rate at which the decline takes place dependent upon the reaction temperature except $\text{AlPO}_4\text{-5}$, which was at a rather high level at first and remained nearly unchanged later. It is interesting that the FWHM decreases to almost the same value within the study

range. The phenomena was inconsistent with the observation with SEM results observed in *ex situ* studies, from which the particle size can be obtained. The size calculated from XRD spectra was crystallite size, while the particles observed in SEM picture was the aggregates of those small crystallites. The aggregating degree was different for CrAPO-5 with different chromium content, so the particle size calculated from SEM pictures was different.

The rate constants k for different crystallization process showed a perfect linear relationship with the molar ratio of Cr/P in the gel, as shown in Fig. 4b. It is generally accepted that as n becomes larger, the rate of formation of nucleation sites becomes increasingly important in determining the overall rate of crystallization. Similar to the crystallization of CoAPO-5 ,⁵ for CrAPO-5 the higher value of n parameter of *ca.* 1.3 indicates the following possible mechanism: CrAPO-5 crystallized with the same 1D mechanism as pure $\text{AlPO}_4\text{-5}$ but the presence of chromium slowed down the nucleation and crystallization rate severely. The prolonged induction time and decreased k constant indicate that the inhibitory effect for both the two stages is proportional to the Cr ions content in the synthesis gels.

Fig. 5a–d exhibited the observed and calculated crystallization curves at different temperature, whereas the plot of the evolution of FWHM of the (100) Bragg reflection as a function of time is shown in Fig. 5e–h. It is consistent with former works that the crystallization rate was proportional to the temperature. Furthermore, the growth profiles for each phase showed little variation with temperature, which we conclude is the evidence that the growth mechanism is not temperature-dependent for the range of temperatures studied. As described above, the FWHM decreased very sharply up to a point that coincided approximately with the change in rate of the reaction and remained effectively constant until the extent of the reaction reaches α maximum observed in Fig. 5a–d. The sharp variations of FWHM during the crystallite growth were larger for CrAPO-5 than that for $\text{AlPO}_4\text{-5}$, which was also observed in the crystallization process of CoAPO-5 .⁵ Furthermore, the reduction became larger when the experimental temperature decreased. As has been proved in laboratory experiment that lower crystalline temperature is benefit for the formation of smaller crystals. The

crystal size has relation to the FWHM to some extent, that is to say, the smaller the crystal size is, the larger the FWHM will be. The changes observed in the *in situ* experiments gave similar trend.

The general Arrhenius expression, $k = A \exp(-E_a/RT)$, was used for the extraction of apparent activation energies for the crystal growth (see Fig. 6a and Table 2). As expected, the

apparent activation energy for the crystal growth increased significantly with the introduction of Cr ions into pure AlPO₄-5. It had a fair linear relationships between the apparent activation energy and the content of Cr³⁺ ions in the scope of the study. The increased apparent activation energy reflect the increasing difficulty for the prepared gels to crystallize.

Fig. 6 (a) Arrhenius plots for determination of activation energies for the crystallization of CrAPO-5 at different temperature; (b) the plot of the apparent activation energy E_a of crystal growth versus the molar ratio of Cr/P in the gel.

3.1.3 Isothermal experiments: analysis of the crystal structure parameters. We analyzed the HRXRD data in detail to extract the unit cell parameters and crystallite sizes of each crystalline AFI phase employing a fundamental parameter approach using Jade 6.5 with the initial unit cell parameters taken from the PDF card of #39-0216 ($a (=b) = 13.713 \text{ \AA}$, $c = 8.427 \text{ \AA}$, $\alpha (= \beta) = 90^\circ$, $\gamma = 120^\circ$ and space group $P6cc$). Interesting additional information on the structural aspects during the growth process was yielded from the results. From this study, considering the peak at degrees, average particle size has been estimated by using Debye-Scherrer formula.⁵⁴⁻⁵⁶

$$D = K\lambda/\beta \cos \theta \quad (2)$$

where ' K ' is a dimensionless shape factor, with a value close to unity. The shape factor has a typical value of about 0.89, ' λ ' is the wavelength of X-ray (0.154 nm), ' β ' is the FWHM (full width at half maximum), ' θ ' is the diffraction angle and ' D ' is particle diameter size. Because all of the crystallization cells used in the *in situ* experiment were not exactly the same and the peak position was not corrected, so the comparison between each experiments were not exactly reliable, but the change during one crystallization process could be fully trustable. The calculated particle size details are shown in Fig. 7. Results show that

Fig. 7 The variation in the grain size of the AFI crystals plotted against crystallization time.

Cr³⁺-substituted aluminophosphate molecular sieves undergone very different changes during the crystallization compared with pure AlPO₄-5 and Co²⁺- or Zn²⁺-substituted ones.⁴¹ The crystallite size of AlPO₄-5 ranged between about 90–105 nm, and grew by approximately 14% during the hydrothermal crystallization. CrAPO-5(0.01) showed similar changes in the crystallite size during the hydrothermal crystallization, but with larger starting initial particle size. When the Cr³⁺ content increased, in other words, when the molar ratio of Cr/P was equal to or greater than 0.05, the hydrothermal crystallization displayed very different variation. The crystallite size ranged from about 50 nm at the beginning, and grew to almost the same level compared with AlPO₄-5 and CrAPO-5(0.01), which gave about 50% growth during the hydrothermal crystallization. The introduction of Cr³⁺ might resulted in different crystallization mechanism compared with Co²⁺- or Zn²⁺-substituted aluminophosphate molecular sieves.⁴¹ The considerable higher changes in the grain size of CrAPO-5 might relate to the interaction between Cr³⁺ ions and the framework, which resulted in the trap of Cr³⁺ into the AlPO₄-5 framework after the build-up of microporous structure.

The plots of the $a (=b)$ and c parameters over crystallization time including the cell volume at 150 °C were shown in Fig. 8. The $a (=b)$ parameter remained nearly constant with a little decrease during the crystallization process and was found to increase with Cr³⁺ content. The values are 13.765 Å (CrAPO-5(0.01)), 13.816 Å (CrAPO-5(0.05)) and 13.817 Å (CrAPO-5(0.08)). The value was larger than that of Co²⁺- or Zn²⁺-substituted aluminophosphates.⁴¹ Compared to un-substituted AlPO₄-5, 13.716 Å, the greater $a (=b)$ parameters indicated that the metal ions was part of the framework, which could result in the lattice expansion. Furthermore, the lattice expansion was limited, which might relate to the amount of Cr³⁺ interacted with the framework was limited. It is to say that there is a highest amount of metal ions that could interact with the framework P atoms. The redundant metal ions are located in other extra-framework sites which have little influence to the structure change of the crystals. Octahedral coordinated Cr³⁺ cation has larger ionic radii, 0.615 Å, compared to Co(II), Zn(II) and Al(III) which have the ionic radii of 0.58 Å, 0.60 Å and 0.39 Å, respectively,^{57,58} therefore the larger

Fig. 8 Variation in the lattice parameters obtained from HRXRD data recorded at the 4B9A (BSRF) beamline, as a function of time during the crystallization process; (A) shows *a(=b)* parameter change, (B) is the *c* parameter variation and (C) is the change in the cell volume over crystallization time. The analysis was performed only on data when the peak reflections were observed obviously.

expansion in the *a(=b)* direction is observed when a metal ion is trapped into the framework.

The change trend of *c* parameter is in contrast to that of *a(=b)* parameter. The *c* parameter was found to increase over crystallization time, more predominantly for un-substituted AlPO₄-5 (by approximately 0.04 Å) compared to CrAPO-5 (increase of 0.01 Å). The increase in *c* parameter during the crystallization process could be ascribed to the uptake of water molecular and the template orientation, as explained by Sankar.⁴¹ The increase in the *c* parameter, over the crystallization time, was due to the uptake of water molecules which may coordinate to Al³⁺ ions accessible in the channel direction, increasing the Al–O bond distance from 1.74 Å for tetrahedral Al³⁺ up to 1.9 Å for an octahedral environment; the more hydrophilic pure AlPO₄-5 (the electronegativity of Al³⁺, Cr³⁺, Co²⁺, and Zn²⁺ are 26.72, 14.41, 9.10 and 10.38, respectively.⁵⁹) should therefore show a larger increase in the *c* parameter compared to MeAPO-5. On the other hand the template orientation within the structure could also play a role in this change in *c* parameter and cell volume. From these findings we can conclude that partial of Cr³⁺ ions in the gel was trapped into the AlPO₄-5 framework in such a way as to cause an expansion in the *a(=b)* direction, which is perpendicular to the channel direction. A change in the *c* parameter and cell volume illustrates the flexibility of the AFI framework.

4. Conclusions

In this study, we have *in situ* investigated the kinetics and the structural parameters of AFI type CrAPO-5, particularly the variation in lattice constants, with time-resolved HRXRPD during the classical hydrothermal synthesis. Information extracted from the *in situ* HPXRPD experiment illustrates that the introduction of Cr³⁺ into pure AlPO₄-5 influenced much on the crystallization process not only on the crystallization velocity, but also on the structural parameters. The crystallization was retarded severely by introducing Cr ions into the AlPO₄-5 gels. The more the Cr³⁺ ions was in the gels, the stronger the inhibitory effect was. There was an interesting discovery that linear relationship was existed between the apparent activation energy and the Cr³⁺ content in the gels. The calculated Avrami exponent *n* was in the range of 1 to 1.3, which implied the similar 1D growth mechanism as that of AlPO₄-5. The extracted structural parameters showed obviously crystal expansion, which was might be caused by the interaction between the framework P and [Cr(H₂O)₆]³⁺ ions, which need to be further studied.
