Graphene/TiO₂ hybrid layer for simultaneous detection and degradation by a one-step transfer and integration method†

Xinxin Yu,^{‡*a} Ranran Cai,^{‡a} Yuqing Song,^c Qiang Gao,^a Nan Pan,^b Mingzai Wu^a and Xiaoping Wang^{bc}

During the past decades, researchers have made great efforts towards an ideal surface enhanced Raman spectroscopy (SERS) substrate. Here a smart SERS-active flexible substrate was designed and its performance was studied. The substrate is constructed from graphene and TiO₂, and could be divided into two functional layers. Graphene provides a flat hot surface for Raman enhancement, which could be ascribed to chemical enhancement. The TiO₂ layer is an effective photocatalyst, which could induce photocatalytic decomposition of adsorbed molecules under UV irradiation. Notably, the substrate was realized by a one-step transfer method, followed by annealing. In the synthesis process, a flexible TiO₂ layer was produced by spin-coating on the CVD graphene and was used as a support in the transfer process of graphene instead of PMMA, which could exclude contamination and avoid degradation of the Raman enhancement performance. Combining detection with degradation of trace amounts of analyte, the versatility of the SERS substrate is greatly enhanced and could be adapted to fit a wide range of sensing and photocatalytic applications.

1. Introduction

Surface-enhanced Raman scattering has been widely investigated as an effective and non-destructive technology for trace detection.^{1–3} Many efforts have been made in the development of SERS-active substrates, which could enhance the information of an analyte adsorbed on the substrate and thus achieve a sensitivity down to the single molecule level. Noble metal nanostructures, such as those made of Au and Ag, have shown excellent SERS activity based on electromagnetic mechanism, which could be ascribed to the localized surface plasmon resonance.⁴ However, such a substrate based on a noble metal is high-cost and usually involves lithography or other complicated nanotechnology for high controllability and repeatability.^{5,6} New structured materials and composites have been explored and synthesized for cost-effective and reusable SERS substrates.⁷

Recently, Raman enhancement effect was observed on two-dimensional layered materials, such as graphene, boron

nitride and MoS₂.^{8,9} Absence of the electromagnetic mechanism (EM), such enhancement could be ascribed to chemical mechanism (CM), which is related with chemical interaction between the adsorbate and the substrate. Although the enhancement factor of CM is smaller than EM, two-dimensional layered materials are still thought to be strong candidates for fundamental study of CM as well as the development of low-cost, green and versatile Raman substrates to meet practical application requirements.¹⁰ Compared with BN and transition metal dichalcogenides, the Fermi energy and surface structure of graphene could be easily modified, thus its enhancement factor could be further promoted.^{11–13} Besides, graphene could be easily modified and processed. Combining with noble metal or semiconductor nanoparticles, the performance, reusability and versatility of graphene could be further improved.^{14–16} It would be much more attractive for applications that a substrate based on graphene could combine simultaneous detection and degradation. To the best of our knowledge, Such studies are still limited.

TiO₂ is inexpensive, nontoxic and highly effective semiconductor as a photocatalyst.^{17–20} Under excitation, electron-hole pairs are generated. After effective charge separation and transfer, reduction and oxidation of organic compounds can be initiated. And it has been proved that the introduction of graphene and CNT is effective route for the improvement of the photocatalytic activity of TiO₂.^{21–24} TiO₂ could be synthesized by chemical template method, electrochemical method and hydrothermal method *etc.*^{25,26} Among them, sol-gel method is

‡ These two authors contribute equally to this work.

one way which is compatible with spin coating.²⁷ After annealing of TiO₂ sol, TiO₂ film can be obtained. In addition to its flexibility, the TiO₂ thin film is stable in the copper etchant solution. Thus the TiO₂ thin film could be used as the supporting layer for graphene. What is more, the TiO₂-coated graphene film can be directly used as multifunctional film after the transfer process, which could realized simultaneous detection and degradation. During the whole process of the preparation, no external contamination is introduced.

In this work, we employ a one-step transfer and integration method to produce a TiO₂/graphene hybrid layer and used it as a multifunctional film for simultaneous detection and degradation. Its photocatalysis and Raman enhancement performance are carefully characterized. Compared with Ag-TiO₂ as well as reported graphene-TiO₂-Ag, we construct a green, uniform, versatile and clean SERS substrate based on CVD graphene *via* a much simple, low-cost method.

2. Experimental

2.1 Materials

Rhodamine 6G (R105624) and Titanium butoxide (T104104) were purchased from Aladdin. Ethanol, acetic acid and hydrochloric acid were purchased from Sinopharm Chemical Reagent Co., Ltd. All the reagents used in this work were analytical grade and used as-received without any purification. The water used in this study was deionized and doubly distilled.

2.2 Sample preparation

Monolayer graphene was grown by atmosphere pressure chemical vapor deposition (APCVD) of methane on a 25 μm thick polycrystalline copper foil (Alfa Aesar, No. 46365). Prior to growth, the copper foil was etched with FeCl₃ aqueous solution (5 g FeCl₃·6H₂O, 10 ml HCl, 100 ml deionized water) and cleaned with ethanol and acetone to remove surface natural oxide layer and surface contaminants. Then, the copper foil was transferred into the CVD chamber and heated up to 1045 °C in a 270 sccm argon. In the growth stage, a flowing gas mixture of CH₄/Ar (406 ppm CH₄, 15 sccm), H₂ (8 sccm, 99.999%) and Ar (247 sccm, 99.999%) was fed into the chamber and graphene could directly formed on the Cu foil at 1045 °C. After a growth time of 4 h, the sample was rapidly cooled down to room temperature by simply pushing the furnace away from it.

Instead of PMMA, a TiO₂ sol prepared by a sol-gel process was used as a supporting layer for the transfer of graphene. In a typical process, 5 ml titanium butoxide was added to 17.5 ml ethanol. After stirring for 10 min, faint yellow solution was obtained and labeled as solution A. Then added 2 ml acetic acid and 5 ml deionized water to another 17.5 ml ethanol. After vigorous stirring, added a drop of hydrochloric acid and labeled as solution B. Added the solution A to solution B drop by drop and kept stirring for 30 min. Then let the solution stand to obtain TiO₂ sol. After spin-coating at 3000 rpm for 40 s, TiO₂ layer on the top of graphene was obtained by curing the TiO₂ sol at 300 °C for 1 h. Next, the copper foil was etched away by 1 g ml⁻¹ FeCl₃ solution. The resulting graphene/TiO₂ film was

washed three times with water, transferred to R6G aqueous solution at certain concentration and float on the surface of the solution for 0.5 h to adsorb R6G molecule.

The graphene transferred by PMMA (950 K A4, 4 wt%, Micro Chem) was also prepared for comparison. After etching the underlying copper foil, the resulting graphene/PMMA film was thoroughly washed and transferred to R6G aqueous solution at certain concentration for the adsorption of molecule. Then picked up the graphene/PMMA film with SiO₂/Si substrate, and remove the PMMA with acetone. Finally the graphene film was washed with ethanol and water for further characterization.

2.3 Sample characterization

X-ray diffraction (XRD) patterns were recorded by a X-ray polycrystalline diffractometer (SmartLab 9 kW) using Cu radiation (40 kV, 100 mA). Field emission-scanning electron microscopy images were taken on Sirion200, FEI microscope operating at 5.0 kV. The Raman enhancement was characterized using a Renishaw Raman microscope equipped with 532 nm argon ion laser excitation source. The laser power is 10% and the power density is about 1.5 mW μm⁻². The spectra in comparison were normalized to the peak at ~520 cm⁻¹, which comes from the SiO₂/Si substrate. The XPS measurements were performed using an ESCALAB 250Xi X-ray photoelectron spectrometer.

3. Results and discussion

Graphene was prepared *via* APCVD method. After a growth of 4 h, monolayer of graphene was obtained on the surface of copper foil. The size of single crystal could be several millimeters. With a much stronger 2D peak compared to G peak, the thickness could be verified by its typical Raman fingerprint of monolayer graphene, as shown in Fig. 1a. In a typical process of transfer, PMMA was usually employed as a support layer. However, the exhaustive removal of PMMA is a major challenge, which would have significant influence on the intrinsic property of graphene and degrade its performance. Search for a various supporting layer is obviously necessary. As an effective photocatalyst, TiO₂ is intensively studied and widely used. It is reported that it is also resistant to copper etchant.²⁷ When it is in the form of thin film, it could be flexible. With all these advantages, TiO₂ not only could be a substitute of supporting layer in the transfer process of graphene, but could form a multifunctional hybrid layer by one-step. Instead of being a disturbing contaminant, the supporting layer is turned out to be a layer of photocatalyst, which does not needed to be thoroughly removed anymore. With this in mind, we take use of sol-gel method to produce the TiO₂ thin layer. As the TiO₂ sol is fluid, thin TiO₂ sol film could be obtained by spin-coating method, which is compatible with existing transfer process of graphene. After being annealed at 300 °C, the TiO₂ sol film condensed into TiO₂ layer. Several unambiguous peaks can be observed in the X-ray diffraction pattern, which clearly reveals a typical crystalline anatase phase (Fig. 1b). Based on the Scherrer equation, we calculated the size of TiO₂ and found it to

Fig. 1 (a) Raman spectra for single layer graphene produced by CVD method. (b) The XRD patterns of TiO_2 produced by sol-gel method followed by annealing at $300\text{ }^\circ\text{C}$ for 1 h.

be about 10.3 nm. The size of TiO_2 calculated from XRD is relatively small, which is consistent with the SEM image in Fig. 2b. The small size might be limited by the relatively low preparation temperature and calcination temperature. To investigate its photocatalysis performance, the photocatalytic

activity evaluation of TiO_2 powder prepared by the same method was carried out. The result is provided in the ESI (Fig. S1†). It could be found that the photo-degradation percentage for the TiO_2 powder is 28%, 55%, 78% and 93%, respectively after 10 min, 20 min, 30 min and 40 min irradiation. Compared with

Fig. 2 (a) The SEM image of graphene on SiO_2/Si substrate transferred by PMMA, (b) the SEM image of pure TiO_2 film produced by sol-gel method followed by annealing at $300\text{ }^\circ\text{C}$ for 1 h. (c) The SEM image of graphene- TiO_2 produced by sol-gel method followed by annealing at $300\text{ }^\circ\text{C}$ for 1 h. (d) Enlarged SEM image of graphene- TiO_2 . (e) The corresponding EDS mapping for Ti, Si, C and O respectively for the same area in (d). The red rectangles in c and d indicate the wrinkles of graphene.

the reported results, the photocatalysis performance of the TiO₂ is acceptable.²⁸ Thus, although the size of TiO₂ calculated from XRD is small, it could be an effective photocatalyst in the hybrid film.

Free of dangling bond, CVD graphene surface is hydrophobic with a surface free energy of 46.7 mJ m⁻². Whereas, the TiO₂ sol is hydrophilic with a surface free energy of 89 mJ m⁻², as demonstrated in ref. 29. When the TiO₂ sol was directly coated on the surface of graphene, dewetting occurred because of the disparity in the surface energies. Hence, cracks appear on the TiO₂ layer after the thermal treatment, as shown in Fig. 2c. As wrinkle is a characteristic feature of transferred CVD graphene as shown in Fig. 2a, the existence of graphene can be identified in the graphene-TiO₂ hybrid film from the cracks (Fig. 2c and d). Besides, a EDS mapping has been provided for the characterization of the microstructure (Fig. 2e). Based on the feature of Ti element mapping, the TiO₂ layer can be identified. The C element mapping implies that there might be some residual carbon on the TiO₂ layer after the annealing process. As the EDS mapping did on the SiO₂/Si substrate, the Si and O elements can also be found.

To investigate whether graphene-TiO₂ hybrid layer can be used as a substrate for Raman enhancement, the Raman spectra of molecules adsorbed on graphene-TiO₂ hybrid layer were collected. In a typical process, Cu foil with graphene and TiO₂ layer was transferred into etching solution. After thorough remove of the Cu foil, graphene coated with TiO₂ layer was obtained, which is floating on the surface of the etching solution. Then, graphene coated with TiO₂ layer was washed with water for three times and transferred to R6G aqueous solution with a series of concentrations from 1 × 10⁻⁶ M to 5 × 10⁻⁸ M for molecule adsorption. Finally, such hybrid layer was picked up by SiO₂/Si substrate, the Raman signal of molecule adsorbed on graphene was collected. As shown in Fig. 5, Raman peaks at 613, 773, 1182, 1307, 1361, 1505, 1647 cm⁻¹ are detected. Compared the two spectra in Fig. 5, it is found that features of the Raman spectroscopy are different. On the surface of graphene transferred by PMMA, peak at 1647 cm⁻¹ is the strongest peak; however, on the surface of graphene-TiO₂ hybrid layer, peak at 613 cm⁻¹ is the strongest peak. After excluding the

hybrid layer, signals of the adsorbed molecule can only be detected on the cracks. A scheme of the preparation and characterization process for the graphene-TiO₂ hybrid film can be found in Fig. 3.

As shown in Fig. 4, the intensities of the Raman signals of the molecules on graphene decrease with the decrease in the concentration of solutions. Under concentration as low as 1 × 10⁻⁷ M, the Raman spectra keep whole characteristic peaks unambiguous. When the concentration decrease to 5 × 10⁻⁸ M, several characteristic peaks from the molecules can still be observed, such as 613, 1360 and 1647 cm⁻¹. The concentration as low as 5 × 10⁻⁸ M is comparable with the concentration used in the classical SERS experiments. The appearance of the Raman signals for molecules on graphene under very low concentrations suggests that the graphene-TiO₂ hybrid layer have Raman enhancement effect. Moreover, these results show that the graphene-TiO₂ hybrid layer Raman enhancement effect should come from graphene.

TiO₂ is wide band-gap semiconductor and it is reported that TiO₂ could bring p-doping to graphene.²⁷ Using TiO₂ as a support layer, some change might be brought to the electronic structure of graphene and has some unknown influence on the Raman enhancement performance. In order to examine the effect of the TiO₂ layer on the Raman enhancement of graphene, we characterized the SERS performance of the hybrid layer and compared it with that of graphene transferred with PMMA. The graphene-TiO₂ hybrid layer and graphene transferred with PMMA are both used as surface enhanced Raman substrate respectively. In a typical process, the surface enhanced Raman substrate was transfer to 1 × 10⁻⁶ M R6G aqueous solution and float on the surface of the solution for 0.5 h. After being picked up by SiO₂/Si substrate, the Raman signal of molecule adsorbed on graphene was collected. As shown in Fig. 5, Raman peaks at 613, 773, 1182, 1307, 1361, 1505, 1647 cm⁻¹ are detected. Compared the two spectra in Fig. 5, it is found that features of the Raman spectroscopy are different. On the surface of graphene transferred by PMMA, peak at 1647 cm⁻¹ is the strongest peak; however, on the surface of graphene-TiO₂ hybrid layer, peak at 613 cm⁻¹ is the strongest peak. After excluding the

Fig. 3 The scheme of the preparation and Raman characterization process for the graphene-TiO₂ hybrid film.

interference of fluorescence background, it seems that peaks at low wave numbers are even stronger than those at high wave numbers on the surface of graphene-TiO₂ hybrid layer. In the literature, peak at 613 cm⁻¹ could be assigned to C_x-C_x-C_x bend and peak at 773 cm⁻¹ could be assigned to out-of-plane C_x-H bend, while peaks at 1182, 1307, 1361, 1505, 1647 cm⁻¹ could be assigned to aromatic C-C stretching.³⁰ Thus, graphene-TiO₂ hybrid layer and graphene transferred by PMMA have different vibration-dependent Raman enhancement behavior. Here, we would give our speculation. With smooth surface and surface plasmon in the range of terahertz, the Raman enhancement effect of graphene can only originate from chemical mechanism.³¹ It is reported that the enhancement of different vibration modes could be ascribed to the dependence on the geometry of the molecules and the surface properties of Raman enhancement substrate.^{8,9,32} In accordance to previous reports, the R6G molecule adsorbs on the surface of graphene by π - π stacking. After the introduction of TiO₂, the interaction between graphene and TiO₂ would change the surface bonding properties of graphene and induce the surface polarization. Thus the interaction between graphene and R6G molecule would be changed, and probably even the geometry of the molecules on the surface. Such vibration dependence behavior of Raman enhancement is consistent with the chemical enhancement mechanism. To further study the interactions between TiO₂ and graphene, XPS on the carbon K-edge is exploited to investigate the surface property as well as its evolution of graphene. The carbon K-edge XPS spectrum of graphene is given in Fig. S2.† In the XPS spectrum of graphene transferred by PMMA, a peak of sp² carbon centered at 284.7 eV can be found, while the C 1s spectrum of graphene/TiO₂ hybrid layer can be fitted by three components: a peak of sp² carbon centered at 284.7 eV (P1), a weak peak at about 286.0 eV (P2) and another notable peak at 288.8 eV (P3). The observed large intensity of P1 implies that the structure of the basic graphene framework has been preserved in the graphene/TiO₂ hybrid layer, while P2 and P3 peak might

originate from sp³ hybridized carbon as well as other oxygen-containing groups. On the basis of previous studies, the oxygen-containing groups might induce larger surface dipoles.³³ It is worth mentioning that graphene-TiO₂ hybrid layer is probably better for application after further improvement of the Raman enhancement factor. As the D and G peaks of graphene overlap and interfere with the high-wave-number peaks, a much intense peak laying at low wave numbers would benefit the study of trace detection and the calculation of enhancement factor.

Although TiO₂ has no Raman enhancement for molecules, it could help develop a semiconductor-graphene system that combine the unique, yet complementary properties of either component to create a multipurpose device. In the rational designed hybrid structure, TiO₂ is an effective photocatalyst, while graphene could enhance Raman signals for molecules and further promote the photocatalytic process for its outstanding charge-carrier transport property. After the remove of the Cu foil, a free standing graphene/TiO₂ hybrid layer can be obtained, which can be transferred to various substrates (even the surface is uneven/curved), sense and degrade analyte *in situ*. In order to illustrate this point more clearly, we deposit a layer of R6G molecules on the SiO₂/Si substrate and then transfer a free standing graphene/TiO₂ hybrid film to it. Then it is found that the signals of the molecules on the surface of SiO₂/Si substrate can be detected unambiguously (blue line in Fig. 6a). Then after 2 hours of irradiation by a 350 W xenon lamp, the molecules can be fully removed, because no signal of the molecule can be found (red line in Fig. 6a). For further investigation, graphene-TiO₂ hybrid layer was soaked in 1 × 10⁻⁶ M R6G aqueous solution for molecule adsorption. After characterization with Raman microscope as shown in Fig. 6b (line 1a), the graphene-TiO₂ hybrid layer was irradiated with xenon light for 1.5 h. The irradiation time was deliberately extended for the complete degradation. It could be found that there is not Raman peaks

Fig. 4 Raman spectra of R6G molecules adsorbed on the surface of graphene-TiO₂ hybrid layer. The graphene were soaked by R6G aqueous solution and the concentration was 1 × 10⁻⁶ M (black line), 5 × 10⁻⁷ M (red line), 1 × 10⁻⁷ M (blue line) and 5 × 10⁻⁸ M (dark cyan line) respectively.

Fig. 5 Raman spectra of R6G molecules adsorbed on the surface of graphene. The black line represents that on graphene transferred by TiO₂ layer and the red line represents that on graphene transferred by PMMA. All of Raman substrates based on graphene were soaked by 1 × 10⁻⁶ M R6G aqueous solution.

Fig. 6 (a) Raman spectra of R6G molecules deposited on the surface of SiO₂/Si substrate detected (blue line) and degraded (red line) with graphene–TiO₂ hybrid layer *in situ*. (b) Raman spectra of R6G molecules adsorbed on the surface of graphene–TiO₂ hybrid layer after five cycles reusability test. The number represent the time of cycle. The peak at 520 cm⁻¹ is from the SiO₂/Si substrate.

of R6G in line 1b after irradiation, which means that the molecules have been totally removed. In Fig. 6b, line 1a (the magenta line, 1a) is the Raman spectra for the first cycle. Then the irradiated graphene–TiO₂ hybrid layer was soaked in R6G aqueous solution of the same concentration and the Raman signals for molecules was collected under the same experiment conditions once more. The dark cyan line (line 2) in Fig. 6b is the Raman spectrum after the re-adsorption process, which exhibit an excellent repeatability. The irradiation and re-adsorption process were repeated five times. In Fig. 6b, Raman spectra from the five cycles of the reusability test could be found. After 3 cycles, the intensities of the Raman peaks decrease to about sixty percent of the initial value and the vibration dependent Raman enhancement become to be similar with that of pure graphene. Such changes are supposed to be owing to the loss of TiO₂ flakes for the weak surface interaction between graphene and TiO₂, which should be further optimized in the following work.

4. Conclusions

During the etching of the underlying copper, TiO₂ was used as the supporting layer for graphene, and thus graphene–TiO₂ hybrid film was prepared by a one-step transfer and integration method. Such hybrid film combines the function of detector and decomposer, which employs the CVD graphene as the SERS-active layer and TiO₂ as the photocatalytic layer. In this study, its sensing and photocatalytic performances were characterized. It is found that its detection limit based on Raman enhancement is 5×10^{-8} M and could thoroughly decompose the contaminant effectively. This novel structure combines the complementary properties of graphene and TiO₂, which is green, low-cost and simple in preparation. The application of it in integrated sensing and photocatalysis should be of value for fitting the wide range of requirements.
