# Nitrogen-doped TiO<sub>2</sub>(B) nanorods as high-performance anode materials for rechargeable sodium-ion batteries

Yingchang Yang,\* Shijia Liao, Wei Shi, Yundong Wu, Renhui Zhang and Senlin Leng\*

To achieve better anode materials for sodium ion batteries, a nitrogen-doped TiO<sub>2</sub>(B) nanorod structure is developed utilizing hydrothermal treatment, ion exchange and a subsequent low temperature calcination process. Transmission electron microscopy, X-ray photoelectron spectroscopy and X-ray diffraction are employed to characterize the structure and properties of the nitrogen-doped TiO<sub>2</sub>(B). Compared with anatase TiO<sub>2</sub> powder (325 mesh) raw materials and the TiO<sub>2</sub>(B) nanorods without N-doping, the as-fabricated nitrogen-doped TiO<sub>2</sub>(B) nanorods with a nitrogen-doping amount of 1.23 atom% exhibit higher specific capacity (224.5 mA h g<sup>-1</sup>), good cycling stability (the capacity retention ratios after 200 cycles at 2C is 93.4%) and enhanced rate capability (110 mA h g<sup>-1</sup> at 3.35 A g<sup>-1</sup>), which is likely to be associated with enhanced conductivity due to N-doping.

## 1. Introduction

Owing to its intrinsic safety, low cost, long cycle life and environmental friendliness, titanium dioxide (TiO<sub>2</sub>) has attracted widespread attention in the areas of lithium-ion batteries (LIBs), sodium-ion batteries (SIBs) and hybrid supercapacitors.<sup>1–5</sup> Among the polymorphs of TiO<sub>2</sub>, the bronze-phase (TiO<sub>2</sub>(B)), has a unique monoclinic *C2/m* structure with an open tunnel structure parallel to the *b*-axis, which favors rapid lithium-ion intercalation/de-intercalation capability.<sup>6</sup> In contrast to LIBs, room-temperature the SIB has gained more interest in large-scale energy storage systems because of the greater abundance and lower cost of sodium-containing precursors in recent years.<sup>7</sup> In 2013, the feasibility of electrochemical sodium storage of TiO<sub>2</sub>(B) nanotubes was first investigated as anodes for SIBs.<sup>8</sup> These TiO<sub>2</sub>(B) nanotubes designed by Huang *et al.* with large interlayer spacing (0.56 nm) of the (001) plane could deliver a discharge capacity of 50 mA h g<sup>-1</sup> at 40 mA g<sup>-1</sup> after 90 cycles. And then, Wu *et al.* reported a noodle-like nanocrystalline TiO<sub>2</sub>(B) fabricated through hydrolysis of TiCl<sub>3</sub> using a mixture of ethylene glycol and water at moderate temperature for anode materials of SIBs.<sup>9</sup> The reversible capacity of this nanocrystalline TiO<sub>2</sub>(B) can reach to about 100 mA h g<sup>-1</sup> at 33.5 mA g<sup>-1</sup> over 70 cycles and the rate capability has been improved (50 mA h g<sup>-1</sup> at 3.35 A g<sup>-1</sup>). More recently, TiO<sub>2</sub>-B nanowires developed by Lee *et al.* with a hydrothermal method possessed long and stable cyclability with a specific capacity of 150 mA h g<sup>-1</sup> at 20 mA g<sup>-1</sup> over 50 cycles.<sup>10</sup> These results suggest that TiO<sub>2</sub>-B is a promising candidate anode material for SIB but the rate performance is still

not good enough for applications in large-scale electrochemical storage device.

To improve the rate capability of electrode materials, many strategies such as designing carbon nanocomposite and doping with foreign atoms (N, S, Sn, *et al.*) have been introduced, as the introduction of carbon additive and foreign atom can enhance electron transport.<sup>11–14</sup> For example, Henry *et al.* introduced anatase TiO<sub>2</sub>@C nanocomposites by pyrolysis of cellulose.<sup>11</sup> These composites with improved electrical contact and faster electron/ion transfer show better lithium/sodium storage properties than pure TiO<sub>2</sub> samples. Wu *et al.* reported N-doped ordered mesoporous anatase TiO<sub>2</sub> nanofibers fabricated *via* electrospinning method and subsequent nitridation treatment.<sup>12</sup> This material exhibits superior cycling stability and rate performance when used as an anode material for sodium-ion batteries. Sn-doped anatase TiO<sub>2</sub> nanotubes synthesized by Yan *et al.* through sol-gel method and subsequent hydrothermal process exhibit improved sodium storage performance,<sup>13</sup> due to the increase of electrical conductivity by Sn-doping.

In this paper, hydrothermal treatment, ion exchange and subsequent low temperature calcination process is utilized to design nitrogen-doped TiO<sub>2</sub>(B) with nanorods structure. Ammonium carbonate is used as the nitrogen source. When tested as anode materials for sodium ion battery, the N-doped TiO<sub>2</sub>(B) nanorods show high specific capacity, good rate capability and enhanced cycling performance.

## 2. Experimental section

### 2.1. Chemicals and materials

Carboxymethyl cellulose (CMC), propylene carbonate (PC) and NaClO<sub>4</sub> were purchased from Alfa Aesar. Sodium and

College of Material and Chemical Engineering, Tongren University, Tongren 554300, China. E-mail: yangyc612@gmail.com; 764546880@qq.com

fluoroethylene carbonate (FEC) were bought from Sigma-Aldrich. All other chemicals (purchased from Sinopharm Chemical Reagent Co., Ltd, Shanghai, China) used in this experiment were analytical grade and were used without further purification.

## 2.2. Materials preparation

In a typical synthesis, 1.0 g anatase  $\text{TiO}_2$  powders (325 mesh) were dispersed in 60 ml of a NaOH aqueous solution (10 M) and then transferred into a Teflon-lined stainless steel autoclave and kept at 180 °C for 12 h to obtain  $\text{Na}_2\text{Ti}_3\text{O}_7$  nanorods. Then, the as-obtained  $\text{Na}_2\text{Ti}_3\text{O}_7$  nanorods were immersed in 1 M  $(\text{NH}_4)_2\text{CO}_3$  solution to yield  $(\text{NH}_4)_2\text{Ti}_3\text{O}_7$  nanorods. After ion exchange for 6 h, the sample was rinsed with deionized water to remove the redundant  $\text{NH}_4^+$  and was dried at 60 °C for 12 h. Then, the product was calcined at 350 °C under Ar for 1.5 h to obtain N- $\text{TiO}_2(\text{B})$  nanorods sample. For comparison, the  $\text{TiO}_2(\text{B})$  nanorods sample without N-doping was obtained using 1 M HCl as reagent during the ion exchange process with other conditions unchanged.

## 2.3. Materials characterization

Transmission electron microscopy (TEM) analysis were conducted using a JEM-2100F instrument with an accelerating voltage of 200 kV. Surface compositions were analyzed with an ESCALab250 X-ray photoelectron spectroscopy (XPS). X-ray diffraction (XRD) patterns were obtained with a Rigaku D/max 2550 VB+ 18 kW X-ray diffractometer with Cu K $\alpha$  radiation (0.1542 nm).

## 2.4. Evaluation of Na storage properties

Active materials dried at 60 °C for 24 h in a vacuum oven were mixed with a binder carboxymethyl cellulose (CMC) and Super P at weight ratios of 70 : 15 : 15 in water solvent to form slurry. Then, the resultant slurry was uniformly pasted on Cu foil with a blade. The average mass of the active material in the prepared electrode sheets is 1.5 mg  $\text{cm}^{-2}$ . The calculation of specific capacity is based on the total mass of active materials. These prepared electrode sheets were dried at 100 °C in a vacuum oven for 12 h and pressed under a pressure of approximately 20 MPa. CR2016-type coin cells were assembled inside an mBraun glovebox ( $\text{H}_2\text{O} < 0.5$  ppm,  $\text{O}_2 < 0.5$  ppm) using the metallic sodium counter/reference electrode and a polypropylene separator (Celgard 2400). The electrolyte solution is 1 M  $\text{NaClO}_4$  in propylene carbonate (PC) with 5 vol% FEC additive. Galvanostatic charge/discharge cycles were carried out with an Arbin battery cycler (BT2000) between 3.0 and 0.01 V vs.  $\text{Na}^+/\text{Na}$ . The electrochemical impedance measurements were performed on Solartron Analytical at an AC voltage of 7 mV amplitude in the frequency range of  $10^5$  to  $10^{-2}$  Hz. Cyclic voltammetry (CV) tests were also conducted on Solartron Analytical.

# 3. Results and discussions

## 3.1. Material synthesis and characterization

It is well known that  $\text{TiO}_2$  particles can react with NaOH in strongly alkaline solution and recrystallize into  $\text{Na}_2\text{Ti}_3\text{O}_7$  with

various morphologies like nanorods, nanowires, and nanosheets during the hydrothermal treatment.<sup>15</sup> In this work, ion exchange of  $(\text{NH}_4)_2\text{CO}_3$  with the  $\text{Na}_2\text{Ti}_3\text{O}_7$  nanorods prepared through hydrothermal treatment and subsequent calcination at low temperature are used to fabricate nitrogen-doped  $\text{TiO}_2(\text{B})$  with nanorods structure. For comparison,  $\text{TiO}_2(\text{B})$  nanorods sample without N-doping was also fabricated utilizing 1 M HCl as reagent during the ion exchange process with other conditions unchanged. Fig. 1 displays the XRD patterns of the anatase  $\text{TiO}_2$  powders raw materials, the as-prepared  $\text{TiO}_2(\text{B})$  nanorods, N- $\text{TiO}_2(\text{B})$  nanorods, and the JCPDS standard cards for anatase and bronze  $\text{TiO}_2$ . It is apparently that the raw materials is anatase  $\text{TiO}_2$  and the products are monoclinic  $\text{TiO}_2(\text{B})$ . The major diffraction peaks for N- $\text{TiO}_2(\text{B})$  nanorods at 15.1, 24.8, 28.6, 43.8, 48.3, 57.8, and 67.4 can be indexed to (001), (110), (002), (003), (020), (022) and (023) of metastable monoclinic  $\text{TiO}_2(\text{B})$  (JCPDS no. 46-1237).<sup>16</sup>

Fig. 2 shows the TEM, high-resolution TEM (HRTEM) and the corresponding selected area electron diffraction (SAED) of the N- $\text{TiO}_2(\text{B})$  nanorods and the  $\text{TiO}_2(\text{B})$  nanorods samples. As can be seen in Fig. 2a and b, the N- $\text{TiO}_2(\text{B})$  shows clear rods structures and the rods are hundreds nanometers in length. The HRTEM image given in Fig. 2c displays clear crystal planes in the rods corresponding to the (001) plane and the (110) plane of  $\text{TiO}_2(\text{B})$ . The SAED pattern (Fig. 2d) shows weak diffraction rings corresponding to the (110), (020), (113), (602), and (621) crystalline planes of the bronze  $\text{TiO}_2$ , confirming the formation of polycrystalline  $\text{TiO}_2(\text{B})$ .<sup>6</sup> The TEM and HRTEM images of  $\text{TiO}_2(\text{B})$  sample are given in Fig. 2e and f, displaying similar rod like morphology with the N- $\text{TiO}_2(\text{B})$  sample.

To investigate the nitrogen species and contents of the as-obtained N- $\text{TiO}_2(\text{B})$  rods, XPS was performed to characterize the N- $\text{TiO}_2(\text{B})$  sample. The survey XPS curve (Fig. 3a) confirms the existence of Ti, O and N in the sample, approving the successful doping of nitrogen in  $\text{TiO}_2(\text{B})$ .<sup>17,18</sup> The amount of N species in the N- $\text{TiO}_2(\text{B})$  was calculated to be 1.23 atom%. The

Fig. 1 XRD patterns of the anatase  $\text{TiO}_2$  powders raw materials, the as-prepared  $\text{TiO}_2(\text{B})$  nanorods, N- $\text{TiO}_2(\text{B})$  nanorods, and the JCPDS standard cards for bronze and anatase  $\text{TiO}_2$ .

Fig. 2 TEM (a and b), HRTEM (c) images and SAED pattern (d) of the N-TiO<sub>2</sub>(B) sample. TEM (e) and HRTEM (f) images of TiO<sub>2</sub>(B) sample.

high resolution XPS spectra of Ti 2p and O 1s were shown in Fig. 3b and c. In Fig. 3b, two strong peaks at 458.5 and 464.6 eV are assigned to Ti 2p<sub>3/2</sub> and Ti 2p<sub>1/2</sub>, respectively, which are in agreement with the binding energies of Ti<sup>4+</sup> in the TiO<sub>2</sub> lattice.<sup>17,19</sup> The binding energy of O 1s band (Fig. 3c) at 529.9 eV corresponds to O<sup>2-</sup> in TiO<sub>2</sub> lattice.<sup>17,19</sup> These assignments are in good agreement with the results of N-TiO<sub>2</sub> reported in the recent literatures.<sup>17,19</sup> In order to gain detailed information on the chemical state of N in the N-TiO<sub>2</sub>(B), deconvolution of the N 1s XPS is shown in Fig. 3d. The N 1s peaks at 395.9, 399.5 and

401.8 eV for N-TiO<sub>2</sub>(B) rods can be assigned to the substituted atomic N species in the TiO<sub>2</sub> lattice (Ti-N), interstitial N anions at interstitial site with an O-Ti-N linkage and the molecularly chemisorbed nitrogen atoms located at the interstitial sites of the TiO<sub>2</sub> lattice,<sup>20</sup> respectively. It has been reported that the role of N species on the electrical conductivity of TiO<sub>2</sub> is mainly related to the narrowing of the band gap and the substitutional N plays a key role in narrowing the band gap by elevating the valence band maximum, while the interstitial N can only introduce some localized N 2p states in the gap.<sup>19</sup>

### 3.2. Electrochemical sodium-storage properties

The sodium-storage performance of the as-prepared N-TiO<sub>2</sub>(B) were evaluated in a half-cell using the metallic sodium as the counter/reference electrode. Firstly, cyclic voltammetry (CV), a powerful and sensitive electrochemical method, is utilized to investigate the electrochemical sodiation/desodiation reactions related to fast double-layer capacitance or faradaic redox processes. Fig. 4a depicts CVs of the as-obtained N-TiO<sub>2</sub>(B) rods electrode for the first, second and fifth cycles at a scanning rate of 0.1 mV s<sup>-1</sup> within the voltage range from 3.0 to 0.01 V. In general, no visible peak can be observed in the CV curves, which is consistent with most of the TiO<sub>2</sub> materials,<sup>8,21,22</sup> demonstrating similar electrochemical sodiation/desodiation (redox) ways. During the first cycle, two wide peaks at 0.8 and 0.4 V are

Fig. 4 Cyclic voltammetry (CV) tests of the N-TiO<sub>2</sub>(B) rods electrode (a) and TiO<sub>2</sub>(B) rods electrode (b) for the first, second and fifth cycles at a scanning rate of 0.1 mV s<sup>-1</sup> within the voltage range from 3.0 to 0.01 V vs. Na<sup>+</sup>/Na.

Fig. 3 The survey scan of XPS (a), Ti 2p (b), O 1s (c), and N 1s (d) core level XPS spectra of the N-TiO<sub>2</sub>(B) sample.

observed in the cathodic sweep, and disappeared in the subsequent cycles, which might be associated with the irreversible cathodic decomposition and irreversible side reactions of the electrolyte at the surface of bronze  $\text{TiO}_2$ .<sup>8–10,23</sup> In the subsequent cycles, only broad and weak redox peaks can be observed during the cathodic and anodic scan, respectively, which are probably related to the reduction of  $\text{Ti}^{4+}$  to  $\text{Ti}^{3+}$  and the subsequent oxidation back to  $\text{Ti}^{4+}$ .<sup>9</sup> This phenomenon is obviously different from anatase  $\text{TiO}_2$  and hollandite-type  $\text{TiO}_2$ ,<sup>24,25</sup> however, similar with rutile  $\text{TiO}_2$ .<sup>26,27</sup> Interesting, the anodic and cathodic current are apparently increasing upon cycling, indicating the reversible insertion/extraction of sodium, which is in agreement with the previous works.<sup>28–30</sup> The continuous increase of anodic and cathodic current is probably associated with the kinetically hindered reversible sodiation/desodiation that call for some kind of activation.<sup>31,32</sup> The CV results of the  $\text{TiO}_2(\text{B})$  nanorods electrode are also shown in Fig. 4b for comparison. As can be seen, no noticeable peak can be observed in the CV curves, which is similar with the electrochemical sodiation/desodiation performance of the N- $\text{TiO}_2(\text{B})$  nanorods electrode. However, the anodic and cathodic current of the  $\text{TiO}_2(\text{B})$  electrode decrease upon cycling, indicating some kinds of electrochemical irreversibility for the  $\text{TiO}_2(\text{B})$  electrode.

The cycling stability and rate capability of the N- $\text{TiO}_2(\text{B})$  rods electrode were further tested. Fig. 5a displays the cycling performance of the N- $\text{TiO}_2(\text{B})$  rods electrode at a low current density of  $16.75 \text{ mA g}^{-1}$  ( $0.1\text{C}$ ) within the voltage range of  $3.0\text{--}0.01 \text{ V}$ . It is seen that the initial discharge capacity is  $231.5 \text{ mA h g}^{-1}$ , and a reversible capacity of  $104.3 \text{ mA h g}^{-1}$  can be achieved. Interestingly, the reversible specific capacity gradually increases upon cycling up to  $224.5 \text{ mA h g}^{-1}$ . After 40 cycles, the reversible specific capacity turns to be stable in the following cycles. Such an increase in specific capacity associated with gradual activation of  $\text{TiO}_2$  upon iterative sodiation/desodiation was already reported for Nb-doped rutile  $\text{TiO}_2$ ,<sup>33</sup> anatase  $\text{TiO}_2$ ,<sup>31,32</sup> and amorphous  $\text{TiO}_2$ ,<sup>34</sup> possibly due to a relatively low initial adsorption of sodium ions to the  $\text{TiO}_2$  surface,<sup>31,35</sup> which deserves certainly further investigation by complementary techniques in future. The first coulombic efficiency is calculated to be 45.1%, indicating huge irreversible capacity loss, which is in accordance with most of the  $\text{TiO}_2$  anode materials for sodium ion batteries.<sup>13,16,24,25,27,29,31,36</sup> The origin of the initial huge irreversibility of  $\text{TiO}_2(\text{B})$  anode materials, recently discussed by Wu *et al.*,<sup>9</sup> may be related to electrolyte decomposition and reorganization of  $\text{TiO}_2$  during the initial sodiation. Nevertheless, further studies will have to be carried out in future to define the detailed reasons for this huge irreversible capacity loss in case of  $\text{TiO}_2(\text{B})$ . During the subsequent charge/discharge cycling, the coulombic efficiencies of N- $\text{TiO}_2(\text{B})$  ascend to 98.6% in the 30th cycle, where the sodiation/desodiation process becomes almost reversible. It is noted that after *ca.* 35 cycles the coulombic efficiency occasionally surpasses 100%, which is due to the formation of high impedance short circuits initiated by small dendrites growing on the surface of sodium counter electrode just before the end of desodiation of the  $\text{TiO}_2$  materials. For comparison, the cycling test of anatase  $\text{TiO}_2$  raw materials and  $\text{TiO}_2(\text{B})$  nanorods sample without N-doping at  $16.75 \text{ mA g}^{-1}$

Fig. 5 The cycling performance and coulombic efficiency of the N- $\text{TiO}_2(\text{B})$  rods electrode at a low current density of  $16.75 \text{ mA g}^{-1}$  ( $0.1\text{C}$ ) within the voltage range of  $3.0\text{--}0.01 \text{ V}$  (a). Cycling performance of anatase  $\text{TiO}_2$  raw materials and  $\text{TiO}_2(\text{B})$  nanorods sample without N-doping at  $16.75 \text{ mA g}^{-1}$  (b). Rate capability of N- $\text{TiO}_2(\text{B})$  rods electrode (c).

were also carried out. As shown in Fig. 5b, the reversible specific capacity of anatase  $\text{TiO}_2$  raw materials is lower than  $50 \text{ mA h g}^{-1}$ . The reversible specific capacity of  $\text{TiO}_2(\text{B})$  nanorods sample without N-doping can reach to  $120 \text{ mA h g}^{-1}$ , however, no activation process can be observed during the whole cycling process. It is a notable result that the N- $\text{TiO}_2(\text{B})$  nanorods electrode displayed better electrochemical performance than that of the  $\text{TiO}_2(\text{B})$  nanorods electrode without N-doping. The possible mechanism for the improved performance by N-doping into  $\text{TiO}_2$  can be associated with enhancement of its electronic conductivity. In fact, electrical resistance measurement under a uniaxial press of active material powders demonstrates that the electronic resistivity of the N- $\text{TiO}_2(\text{B})$  pellet ( $2.9 \times 10^3 \Omega \text{ cm}$ ) is much lower than that of  $\text{TiO}_2(\text{B})$  pellet ( $3.3 \times 10^5 \Omega \text{ cm}$ ). After activation of the N- $\text{TiO}_2(\text{B})$  electrode completely, rate capability studies at different current densities was carried out, and the results are summarized in Fig. 5c. The N- $\text{TiO}_2(\text{B})$  electrode can deliver a discharge specific capacity of 223, 205, 188, 168, and  $154 \text{ mA h g}^{-1}$  using a charge and discharge rate of 0.2, 0.5, 1, 2, and 5C ( $1\text{C} = 167.5 \text{ mA g}^{-1}$ ), respectively. Even charge/discharge at high rates of 10 and 20C, this electrode can still carry a discharge specific capacity of 135 and  $110 \text{ mA h g}^{-1}$ , much higher than the previous reports on  $\text{TiO}_2(\text{B})$  based electrodes.<sup>8–10</sup> Notably, the specific capacity can be recovered to the initial value when the current density is reduced back to  $0.1\text{C}$ .

Fig. 6a shows the galvanostatic charge/discharge curves of the N-TiO<sub>2</sub>(B) electrode at different rates. As can be seen that the electrode show a slope profile of the voltage–capacity relationship during both the charge and discharge state at different rates, which are in accordance with the CV curves (Fig. 4). Fig. 6b compares the cycling performance of N-TiO<sub>2</sub>(B) electrode activated at a low current density of 0.1C for 30 cycles and the freshly prepared electrode at a moderate rate of 2C. It is apparent that the reversible capacity of the freshly prepared N-TiO<sub>2</sub>(B) electrode without activation is about 81 mA h g<sup>−1</sup>, much lower than that of the activated electrode (175 mA h g<sup>−1</sup>). In addition, the retention ratios of the activated electrode and electrode without activation after 200 cycles are 93.4 and 83.2%, respectively, indicating the necessity of activation process at low current density.

To evaluate the resistance against electron transfer during the activation process, electrochemical impedance spectroscopy (EIS) measurements of the anatase TiO<sub>2</sub> powder, TiO<sub>2</sub>(B), and N-TiO<sub>2</sub>(B) electrodes were also conducted. To maintain uniformity, EIS measurements were performed at full charge state after the 3rd discharge/charge cycle. Generally, the high-frequency semicircle and the semicircle in the medium-frequency region are attributed to the SEI layer and/or contact resistance, and the charge-transfer impedance on the electrode–electrolyte interface, respectively.<sup>37–39</sup> The linear portion is designated to Warburg impedance which is attributed to the

Fig. 7 Electrochemical impedance spectroscopy (EIS) measurements of the anatase TiO<sub>2</sub> powder, TiO<sub>2</sub>(B), and N-TiO<sub>2</sub>(B) electrodes.

diffusion of sodium ion into the bulk of the electrode materials.<sup>37–39</sup> According to the modified Randles equivalent circuit shown in the inset of Fig. 7, the charge-transfer resistance ( $R_{ct}$ ) of N-TiO<sub>2</sub>(B) electrode is 185.1  $\Omega$ , which is much lower than those of TiO<sub>2</sub> powder electrode (708.7  $\Omega$ ) and TiO<sub>2</sub>(B) electrode (456.3  $\Omega$ ). In addition, the SEI resistance ( $R_s$ ) of N-TiO<sub>2</sub>(B) electrode (8.1  $\Omega$ ) is also lower than those of TiO<sub>2</sub> powder (14.7  $\Omega$ ) and TiO<sub>2</sub>(B) electrode (14.3  $\Omega$ ), revealing better electronic and ionic conduction of N-TiO<sub>2</sub>(B) electrode. It is well-known that better electronic and ionic conduction during cycling means better electrochemical performance, which is consistent with the cycling performance of these electrodes at the same current density.

## 4. Conclusions

In conclusion, nitrogen-doped polycrystalline TiO<sub>2</sub>(B) nanorods with a nitrogen-doping amount of 1.23 atom% have been synthesized through hydrothermal reaction of anatase TiO<sub>2</sub> powders (325 mesh) with concentrated NaOH solutions, ion exchange with (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> and subsequent calcination at 350 °C. Due to the nanostructure design and nitrogen-doping, the N-TiO<sub>2</sub>(B) nanorods used as anode materials for sodium ion battery show a reversible specific capacity up to 224.5 mA h g<sup>−1</sup> after electrochemical activation at low current density. Additionally, the activated N-TiO<sub>2</sub>(B) nanorods electrode exhibits good cycling stability (the capacity retention ratios after 200 cycles at 2C is 93.4%) and enhanced rate capability (110 mA h g<sup>−1</sup> at 3.35 A g<sup>−1</sup>).
