Inverse-architecture perovskite solar cells with 5,6,11,12-tetraphenylnaphthacene as a hole conductor†

Chengxin Wang,^a Hao Hao,^a Shufen Chen,^a Kun Cao,^a Hongtao Yu,^a Qin Zhang,^a Guangjian Wan,^b Wenjuan Shang^{ac} and Wei Huang^{ad}

5,6,11,12-Tetraphenylnaphthacene (rub), an organic small molecular semiconductor widely used in organic field-effect transistors and organic light-emitting diodes, was introduced into MAPbI₃-based inverse-architecture perovskite solar cells as a hole transport layer due to its high hole mobility, good hydrophobic properties, favourable highest occupied molecular orbital (HOMO), low-cost, and low-temperature treatment process of rub. A high open-circuit voltage of 0.96 V, short-circuit current of 22 mA cm⁻², and power conversion efficiency of 14.3% were achieved in the inverted planar heterostructure perovskite solar cells based on the rub hole-transport layer due to the HOMO energy level matching between rub and MAPbI₃, large hole conductivity of rub, and large crystalline grain size of MAPbI₃ formed on rub.

1. Introduction

Organic–inorganic hybrid perovskite solar cells (PSCs) have been demonstrated as one of the most promising and fast growing photovoltaic technologies due to their high efficiency, various photovoltaic architectures, and low-cost manufacture.^{1–3} The power conversion efficiencies PCEs of PSCs based on the hybrid perovskite materials CH₃NH₃PbX₃ (MAPbX₃, X = Cl, Br, or I) have remarkably progressed over the past few years, even in planar heterojunction structures with simple device architectures and easy fabrication processes.^{4,5} The superior photoelectric conversion capability mainly originates from the unique optoelectronic properties, including extremely high optical absorption coefficient,⁶ excellent bipolar carrier transport ability,^{7,8} and low non-radiative recombination rates, of the organic–inorganic hybrid perovskite materials.

In PSCs, the perovskite absorber is typically sandwiched between the electron and hole transport layers (ETL and HTL); thus, careful selection of both the ETL and HTL is critical for

achieving high optoelectronic conversion efficiency due to their important roles in the separation and collection of the photo-generated charge carriers produced in the perovskites. Matching the lowest unoccupied molecular orbital (LUMO) of the ETL and the highest occupied molecular orbital (HOMO) of the HTL respectively with those of the perovskite absorber is beneficial for optimizing the open-circuit voltage (V_{oc}) and dissociating excitons at the interfaces; moreover, high carrier mobilities of these carrier transport layers can effectively transport charge carriers towards the electrodes and avoid the hysteresis phenomenon. The commonly used ETLs include inorganic TiO₂,⁹ ZnO,¹⁰ and organic [6,6]-phenyl-C₆₁-butyric acid methyl ester (PC₆₁BM);¹¹ among these, PC₆₁BM has a relatively high mobility of $\sim 10^{-4}$ cm² V⁻¹ s⁻¹ and is widely used in inverse-architecture PSCs.¹² Among the reported hole-transport materials *e.g.*, CuI,¹³ CuSCN,¹⁴ CuInS₂,¹⁵ CuO_x,¹⁶ Cu-doped NiO,¹⁷ 2,2',7,7'-tetrakis-(*N,N*-di-*p*-methoxyphenylamine)-9,9'-spiro-bifluorene (spiro-OMeTAD),¹⁸ and poly(3,4-ethylene-dioxythiophene):poly(4-styrenesulfonate) (PEDOT:PSS),¹⁹ inorganic hole conductors display high hole mobilities, good chemical stability, and low-cost; however, the PSCs employing these inorganic hole conductors also show disadvantages such as low recombination resistance, high-temperature processing, and poor quality of perovskite film on these thick hole conductors. Kamat *et al.* first reported CuI as an HTL in PSCs and achieved a PCE of 6.0%.²⁰ The low PCE was attributed to the higher recombination occurring at the CuI/perovskite interface. Then, Nazeeruddin *et al.* improved the PCE to 12.4% using CuSCN as a hole conductor in the conventional-architecture PSCs.²¹ CuSCN and NiO have also been explored in inverse-architecture PSCs with PCEs of 3.8% and 9.1%,

respectively.^{22,23} Recently, Jen *et al.* have utilized Cu-doped NiO as a hole-extraction layer and acquired a PCE of 15.4%.²⁴ However, the high-temperature or high-vacuum process used to prepare the NiO_x film to achieve a high PCE cannot meet the requirements for the future development of solution-processable, low-cost, and mass-manufacturable solar cells.

In comparison with inorganic hole conductors, organic hole transport materials have universally low hole mobilities but have the advantages of an adjustable HOMO energy level and low-temperature treatment fabrication process. Among all of the organic hole transport materials including spiro-OMeTAD,²⁵ poly[N,N'-bis(4-butylphenyl)-N,N'-bis(phenyl)benzidine] (poly-TPD),²⁶ triazine-Th-OMeTPA,²⁷ and polytriarylamine (PTAA),²⁸ PEDOT:PSS is a well-known hole conductor and has been commonly used as an efficient interfacial layer for the modification of indium-tin oxide (ITO) anodes in organic light-emitting devices and organic solar cells.^{29–32} Since the first report on PEDOT:PSS in an inverse-architecture PSC by Chen *et al.*,³³ many studies have been reported on the use of PEDOT:PSS for achieving high PCEs and a highest efficiency of 19.1% has been reported.³⁴ However, PEDOT:PSS is not an ideal hole-transport material because of its inefficient electron-blocking capability and the detrimental effects of its intrinsic hygroscopic and acidic nature on the device stability. In addition, the HOMO level of PEDOT:PSS (−(4.9–5.2) eV, depending on the ratio of PEDOT to PSS) is lower than the valence band potential of CH₃NH₃PbI₃ perovskite (∼−5.43 eV); thus, the potential energy loss at the CH₃NH₃PbI₃/PEDOT:PSS interface decreases the built-in potential of the perovskite solar cells and thus generates a low *V*_{oc}. Furthermore, the common combination of PEDOT:PSS with PC₆₁BM as the hole and electron conductor is far from an optimal device structure due to the larger mobility of PC₆₁BM ($2.98 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$) than that of PEDOT:PSS ($1.0 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$).^{35,36} Zhu *et al.* decreased the electron mobility of PC₆₁BM comparable to that of PEDOT:PSS by doping PMMA into PC₆₁BM and demonstrated a high PCE of 18.7%.³⁷

For the abovementioned reasons, the development of alternative hole conductors to PEDOT:PSS is a promising avenue for further improving the performance of inverse-architecture PSCs as PEDOT:PSS likely does not represent an ideal hole-conducting material for this system. Clearly, a promising strategy to achieve high-performance PSCs with a large *V*_{oc} and excellent device stability is to use an organic HTL with high HOMO level, hydrophobic property, and large hole mobility.

In this study, we employed a small-molecular organic semiconductor 5,6,11,12-tetraphenylnaphthacene (rubrene, abbreviated as rub) as the hole conductor in CH₃NH₃PbI₃-based perovskite solar cells due to the following excellent properties of rub. First, as widely reported in organic field-effect transistors,^{38,39} rub has an extremely high hole mobility of $\sim 0.5 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, with which holes can be effectively transported and extracted from the photovoltaic devices. Moreover, rub has a favourable HOMO level (−5.06 eV) with respect to the valence band of perovskite (∼−5.43 eV), which is helpful for obtaining a high *V*_{oc}. Moreover, rub is easily dissolved in conventional organic solvents such as chloroform and chlorobenzene, with

the resulting rub film showing pretty good hydrophobic properties and preventing water vapor entering into the perovskite film. Notably, rub film has extremely low cost when compared with other organic HTLs such as spiro-OMeTAD and PEDOT:PSS; more importantly, it can be solution processed at a low treatment temperature of less than 110 °C, which is compatible with future manufacturing processes of large-area flexible solar cells.

With rub as a single-hole conductor, we manufactured CH₃NH₃PbI₃-based PSCs and achieved the highest PCEs of 13.0% and 14.3% for the forward and reverse scans, respectively, which is higher than 12.4% (forward) and 12.7% (reverse) observed for a conventional PEDOT:PSS. Furthermore, we fabricated a group of PSCs with a bi-HTL of PEDOT:PSS/rub to replace the single rub layer and acquired higher PCEs of 13.7% and 14.4% for the forward and reverse scans, respectively. This study provides new opportunities for the choice of hole transport materials in perovskite solar cells.

2. Experimental details

2.1 Materials

Patterned ITO glasses with a sheet resistance of $7 \Omega \text{ sq}^{-1}$ and a thickness of 1.1 mm were purchased from Hua Yu United Technology Co. Ltd. Lead iodide (PbI₂) and methylammonium iodide (MAI) were purchased from Sigma-Aldrich and Shanghai MaterWin New Materials Co. Ltd, respectively. PEDOT:PSS, rub, and PC₆₁BM were purchased from Heraeus Materials Technology Co. Ltd., Banhe Technology Co. Ltd., and Nano-C, respectively. All solvents used were obtained from Sigma-Aldrich. All materials and solvents were directly used without further purification.

2.2 Device fabrication

ITO glasses were washed with acetone, ethanol, and deionized water in sequence, followed by ultrasonic cleaning with deionized water, acetone, and ethanol for 15 min. After drying with high purity N₂ and vacuum drying in an oven, the ITO substrates were treated with O₃ for 15 min in an UV-ozone cleaner. Then, rub (or PEDOT:PSS) was spin-coated onto the patterned ITO glass substrates at 3000 rpm for 30 s (2000 rpm for 60 s for PEDOT:PSS), forming a 47 nm (50 nm for PEDOT:PSS) thick film, and then dried at 110 °C for 20 min (120 °C for 30 min for PEDOT:PSS). Similar to a single HTL, the bi-HTL of PEDOT:PSS/rub was treated *via* a two-step spin-coating process. Note that rub was dissolved in chlorobenzene at a concentration of 30 mg mL^{−1}. To date, these HTL-coated glasses were moved into a glovebox to form a $\sim 300 \text{ nm}$ MAPbI₃ film *via* a one-step deposition method. The MAPbI₃ solution was prepared by dissolving PbI₂ and MAI (molar ratio of 1 : 1, 40 wt%) into 1 mL of mixed solvent composed of dimethyl sulfoxide (DMSO) and gamma-butyrolactone (GBL) with a volume ratio of 3 : 7 and then stirring at 70 °C for 1 h. The perovskite precursor solution (60 μL) was spin-coated on the HTL at 2500 rpm for 90 s, and then, 300 μL of chlorobenzene was quickly dropped on the perovskite film. The as-prepared films were then annealed at 100 °C for 30 min on a hot plate.

During the annealing process, the samples obviously changed from pale yellow to dark brown. After this, 20 mg mL⁻¹ PC₆₁BM in chlorobenzene was spin-coated onto the perovskite layer at 3000 rpm for 60 s in a N₂ glovebox. Finally, all the samples were transferred to a vacuum chamber for 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) and silver electrode evaporation. Herein, a 6 nm thick BCP and a 100 nm thick Ag were sequentially deposited onto the perovskite layer under a pressure of 6.0×10^{-5} Pa through a shadow mask with a defined device area of ~ 0.1 cm².

2.3 Device characterization

The morphology of the perovskite layer was obtained using a Hitachi S-4800 field emission scanning electron microscope (SEM) and a Bruker atomic force microscope (AFM). The crystal structures of the MAPbI₃ thin films were characterized using the Bruker D8 ADVANCE X-ray diffraction (XRD) equipment. The thicknesses of the PEDOT:PSS, rub, perovskite, and PC₆₁BM films were determined using a Bruker DektakXT Stylus Profiler. The current density–voltage (*J*–*V*) characterization of the perovskite solar cells was carried out using a Keithley 2400 source meter under a simulated AM 1.5 illumination (100 mW cm⁻², Oriel Sol3A 94023A Class Solar Simulator) at a scan rate of 200 mV s⁻¹. The UV-vis absorption spectra of the perovskite films and the transmissivity of different HTLs were obtained using a PerkinElmer Lambda 650S spectrophotometer with an excitation wavelength of 400 nm. The photoluminescence measurements were carried out using a Horiba Fluoromax 4 spectrometer. The impedance characteristics of the devices were measured *via* a Wayne kerr 6500B analyzer. The surface potential of the HTLs (PEDOT:PSS or rub) was measured using a Cypher S atomic force microscope.

3. Results and discussion

3.1 The influence of rub on the optical and electrical properties of the perovskite films

Fig. 1(a) illustrates the structural image of the present inverse-architecture planar perovskite solar cells, in which a rub layer

was applied between the ITO electrode and perovskite photo-active layer to work as an efficient hole selective layer. Rub was chosen as it has extremely high hole mobility (~ 0.5 cm² V⁻¹ s⁻¹) and favourable HOMO level (−5.06 eV). In the control device, rub was replaced with the conventional PEDOT:PSS as the HTL, whereas for the bi-HTL device, rub was replaced with PEDOT:PSS/rub. Scanning Kelvin probe microscopy (SKPM) was employed to determine the surface potential (HOMO level) of the PEDOT:PSS or rub, which helped to reveal the band bending at the perovskite/PEDOT:PSS or perovskite/rub interface in the energy level diagram. The two-dimensional surface potential distributions obtained for the PEDOT:PSS and rub films are shown in Fig. S1.† The HOMO levels of PEDOT:PSS and rub were −4.88 and −5.06 eV, respectively, which were calculated using the formula of $\varphi_s = \varphi_{\text{Tip}} + eV_{\text{CPD}}$ and are summarized in Table S1.† Herein, φ_s is the surface potential of the sample, φ_{Tip} is the tip potential of the yttrium probe, and V_{CPD} is the contact potential difference between the sample and the probe. As observed from the energy level diagram shown in Fig. 1(b), higher HOMO (−5.06 eV) of rub than that of PEDOT:PSS (−4.88 eV) helps to reduce the potential energy loss at the CH₃NH₃PbI₃/HTL interface, and thus, use of rub may generate a higher *V*_{oc} in our PSCs. In addition, the hole and electron conductivities of rub and PEDOT:PSS were calculated using the direct current conductivity equation of $I = \sigma_0 A d^{-1} V$ by designing single-hole and single-electron devices.⁴⁰ The corresponding structures of the single-hole and single-electron device were ITO/PEDOT:PSS (65 nm) or rub (166 nm)/MoO₃ (25 nm)/Ag and ITO/LiF (5 nm)/PEDOT:PSS (65 nm) or rub (166 nm)/LiF (0.8 nm)/Al, as shown in Fig. 2. From the measured electrical properties (Fig. 2(c) and (d)), the hole and electron conductivities of rub were calculated to be 4.96×10^{-2} and 1.55×10^{-5} mS cm⁻¹, respectively, whereas they were 3.66×10^{-3} and 1.01×10^{-3} mS cm⁻¹ for PEDOT:PSS, respectively. Note that the hole conductivity of 4.96×10^{-2} mS cm⁻¹ for rub was much larger than 3.66×10^{-3} mS cm⁻¹ of PEDOT:PSS, demonstrating a more efficient hole transport in the rub-based PSCs. In addition, the extremely low electron conductivity of rub indicates that the electron transport *via* rub towards the anode is almost impossible.

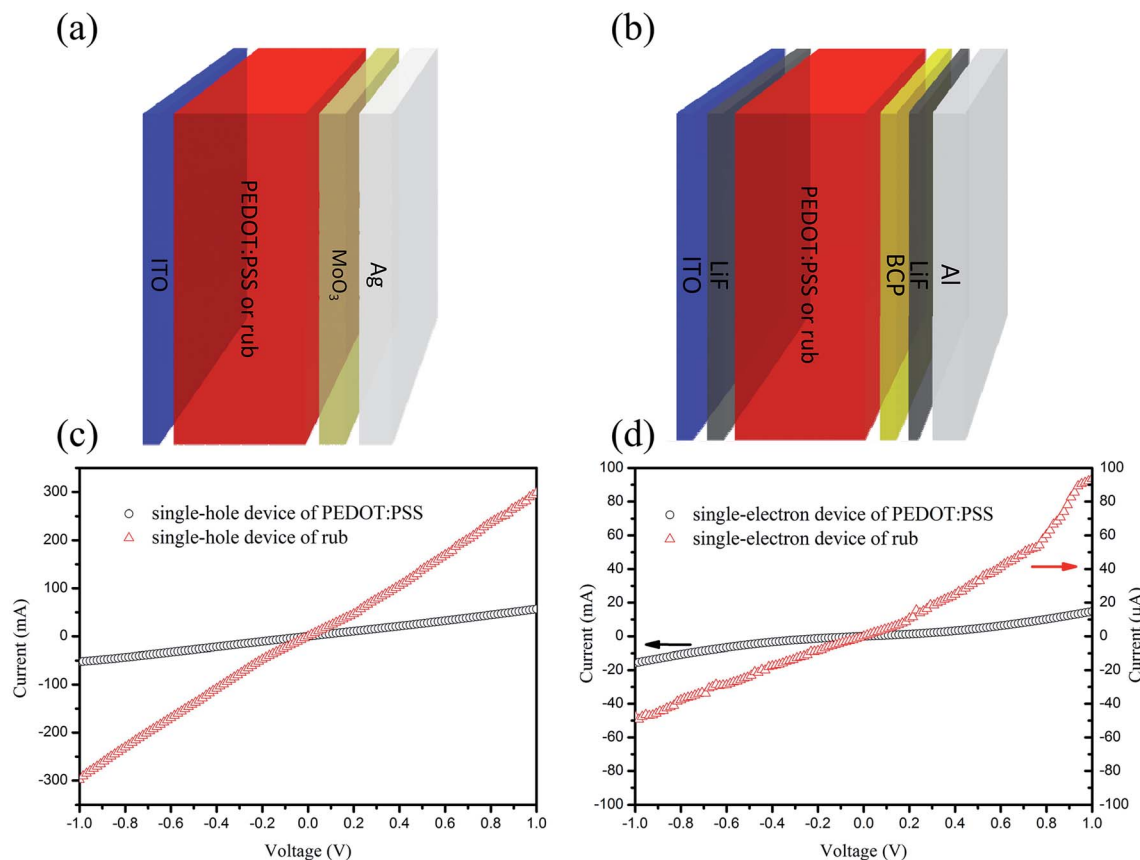

Fig. 2 The structures of (a) single-hole and (b) single-electron devices based on PEDOT:PSS or rub. The current–voltage curves obtained for the (c) single-hole and (d) single-electron devices.

Before introducing rub into the perovskite solar cell, the effect of the optical properties of rub on the perovskite layer was first studied. Fig. 3(a) illustrates the transmissivity characteristics of different HTLs. It can be clearly observed that the rub film has a weak absorption in the visible region, showing a high transmissivity of 87% at 550 nm. While for the PEDOT:PSS layer and the PEDOT:PSS/rub bi-HTL, the transmissivities exhibit a slight decline due to the absorption of PEDOT:PSS in the visible and near-infrared region. The influences of the HTLs on the absorption of the perovskite layer were also investigated, as illustrated in Fig. 3(b). Similar absorption spectra confirm that the absorption of these HTLs was negligible when compared with that of the perovskite layer.

3.2 The morphology and quality of the perovskite films

Fig. 4(a–c) displays the scanning electron microscopy (SEM) images of the surface morphology of the perovskite films on the different HTLs. It is notable that the average crystalline grain size of the perovskite on the rub substrates (208 nm and 234 nm on rub and rub/PEDOT:PSS, respectively) is much larger than that on the PEDOT:PSS substrates (198 nm), as shown in the panels d, e, and f. The non-wetting surface of rub, as shown in Fig. S2,[†] is beneficial for grain growth because of the lower nucleus density and less dragging force.^{41,42} The larger grain size observed on the rub substrates is of importance in suppressing

the grain boundary traps to obtain better device efficiency.⁴³ The panels g, h, and i of Fig. 4 show the surface morphology of the perovskite films on different HTLs obtained by atomic force microscopy (AFM) in the tapping mode. The calculated surface roughnesses (root mean square, RMS) of the perovskite films are 3.83 nm and 3.19 nm for the samples on rub and PEDOT:PSS/rub, respectively, which are slightly smaller than 4.32 nm observed for those directly deposited on PEDOT:PSS.

Fig. 5 shows the X-ray diffraction (XRD) patterns of the CH₃NH₃PbI₃ films grown on ITO, PEDOT:PSS, rub, and rub/PEDOT:PSS. The peaks at 14.1°, 28.4°, and 42.1° were attributed to the (110), (220), and (330) faces of the CH₃NH₃PbI₃ perovskite crystalline structure, respectively.^{44,45} It was observed that all these perovskite diffraction peaks became significantly enhanced when the perovskite film were formed on rub, which was indicative of the improvement in the crystalline properties of the CH₃NH₃PbI₃ film. The high crystalline quality of the perovskite finally contributes to high short-circuit current (J_{sc}) and thus a high PCE.

3.3 The performance of the PSCs

A batch of inverse-architecture planar heterostructure PSCs was fabricated with different HTLs with their J – V curves illustrated in Fig. 6(a) and parameters summarized in Table 1. It was found that distinct HTLs have significant impacts on the device

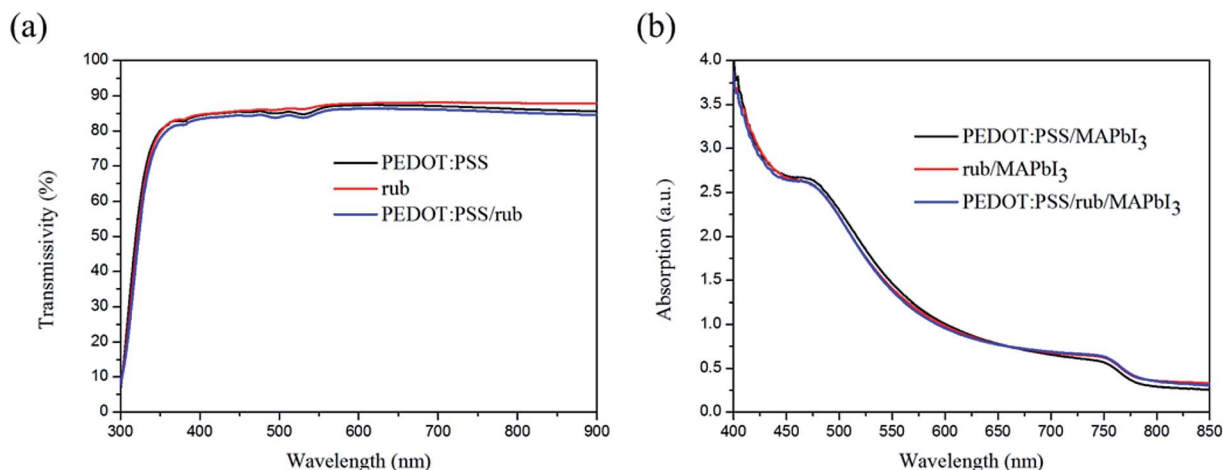

Fig. 3 (a) The transmissivity curves obtained for PEDOT:PSS, rub and PEDOT:PSS/rub. (b) The UV-vis absorption spectra of perovskite on the different HTLs.

performance. As was expected, PSCs using rub as the hole conductor yielded a large V_{oc} of 0.96 V because of the matched HOMO energy levels between rub and the perovskite, which was

larger than 0.81 V found in the PSCs with the PEDOT:PSS HTL. Due to large hole conductivity of rub and improved crystalline quality of the perovskite, the J_{sc} (22.0 mA cm^{-2}) in the rub-based

PSCs was slightly better than 21.4 mA cm⁻² found in the PEDOT:PSS-based PSCs. Despite a decrease in the filling factor (FF) from 73.1% to 67.5%, the rub-based PSCs showed a high PCE of 14.3%, which was slightly larger than 12.7% found in the

PEDOT:PSS-based PSCs. It maintains a high J_{sc} (22.2 mA cm⁻²) in the bi-HTL devices, whereas the V_{oc} in these devices present a compromise between the V_{oc} s in the rub-based and that in the PEDOT:PSS-based PSCs. The resulting PCE reaches 14.4% in the PEDOT:PSS/rub bilayer devices, which is the best among the three groups of PSCs studied herein, as further demonstrated by the external quantum efficiency (EQE) curves shown in Fig. 6(b). It is noteworthy that there exist very small differences for both the current and PCE in the forward and reverse scanning directions (Table 1), indicating an extremely weak hysteresis in all the devices with good crystallinity and phase purity. The statistics on the PCE distribution (Fig. S3†) demonstrated the reliability and repeatability of the PCE enhancement with the use of the rub HTL in the photovoltaic devices. The stability of the cells with different HTLs was also investigated. Note that the as-fabricated devices with different HTLs were stored in an air atmosphere at 25 °C and a humidity of 35% without further encapsulation. From the normalized power conversion efficiency of the devices based on different HTLs as a function of storage time shown in Fig. 6(c), it could be seen that the rub-based and PEDOT:PSS/rub-based devices maintained 82.6% and 86.3% of the initial efficiency when these perovskite solar cells were stored in air atmosphere for 24 hours, better than 73.1% found for the PEDOT:PSS-based device; this indicates

Fig. 6 (a) The J - V characteristics (under AM 1.5 simulated illumination), (b) EQE curves, (c) normalized power conversion efficiency as a function of storage time, and (d) Nyquist plots (under dark conditions at an applied voltage of 0.7 V) of perovskite solar cells with different HTLs. F and R in (a) correspond to the forward and reverse scanning directions, respectively. The inset of (d) is the equivalent circuit.

Table 1 The photovoltaic performance of the PSCs with different HTLs

| HTL | Scan direction | J_{sc} (mA cm ⁻²) | V_{oc} (V) | FF (%) | PCE (%) |
|---------------|----------------|---------------------------------|--------------|--------|---------|
| PEDOT:PSS | Forward | 21.5 | 0.81 | 71.2 | 12.4 |
| | Reverse | 21.4 | 0.81 | 73.1 | 12.7 |
| rub | Forward | 21.4 | 0.93 | 65.1 | 13.0 |
| | Reverse | 22.0 | 0.96 | 67.5 | 14.3 |
| PEDOT:PSS/rub | Forward | 22.1 | 0.85 | 73.4 | 13.7 |
| | Reverse | 22.2 | 0.86 | 74.9 | 14.4 |

that the good hydrophobic properties of rub prevent water vapor entering into the perovskite film.

It is reasonable to believe that rub plays an important role in carrier transport and exciton dissociation; thus, it will display high FF in the rub-based devices. However, reduced FF value was observed in all the devices with a single rub as the hole transport layer. To explore the charge transfer at the interface between the HTLs and the perovskite layer, the perovskite films on the rub layer and those on the PEDOT:PSS layer were fabricated to measure the steady-state and time-resolved transient photoluminescence (PL) spectra. Fig. 7 presents the steady-state and time-resolved transient PL spectra of PEDOT:PSS/perovskite, rub/perovskite, and PEDOT:PSS/rub/perovskite. It can be seen from Fig. 7(a) that the PEDOT:PSS/MAPbI₃ film has a strong PL response, whereas the PL intensities of the rub/MAPbI₃ film and the PEDOT:PSS/rub/MAPbI₃ film obviously decrease. This phenomenon indicates that rub is more effective in transferring charge carriers than PEDOT:PSS. The time-resolved PL measurements also confirm this indication. The PL lifetimes of these two samples were fitted with a bi-exponential decay function including a fast decay and a slow decay process, of which the fast decay process is a consequence of the radiative decay of the free carriers in the perovskite layer and the slow decay process is ascribed to the hole carriers transported from the perovskite layer to the HTLs. The fitted parameters are summarized in Table S2.† The lifetimes that represent a slow decay process are 7.6 ns, 6.9 ns, and 7.2 ns for

PEDOT:PSS/perovskite, rub/perovskite, and PEDOT:PSS/rub/perovskite, respectively, which are in agreement with the steady-state PL results.

To further understand the influence of the rub on the devices, electrochemical impedance spectroscopy (EIS) measurements for the perovskite solar cells with different HTLs were carried out with their Nyquist plots shown in Fig. 6(d). Recombination processes are present in all photovoltaic devices; moreover, the arc observed in the low-frequency region of the Nyquist plots of the perovskite solar cells is associated with the recombination process, which is often described by the recombination resistance (R_{rec}) generated at these contact interfaces inside the rub/perovskite/PC₆₁BM/BCP structure. Since the recombination rate is inversely proportional to R_{rec} , a high R_{rec} represents less recombination and sufficient dissociation of carriers at these interfaces. However, the R_{rec} (362 Ω cm²) shows a slight decrease in the PSCs fabricated with the rub HTL, indicating that serious recombination still occurs at the interfaces of rub/perovskite or PEDOT:PSS/rub although a faster charge carrier transfer process at this interface and a larger hole mobility of rub results in a decreased FF. However, the bi-HTL PSC shows larger R_{rec} (569 Ω cm²) than the PEDOT:PSS-based PSC (435 Ω cm²), excluding the significant recombination at the interface of PEDOT:PSS/rub. This result indicates that a better film morphology of rub was formed on PEDOT:PSS than that directly formed on an ITO electrode.

Fig. 7 (a) The steady-state and (b) time-resolved transient PL spectra of rub/perovskite, PEDOT:PSS/perovskite and PEDOT:PSS/rub/perovskite. The steady-state PL spectra were excited at a wavelength of 400 nm and a peak wavelength of 769 nm was observed.

4. Conclusions

In summary, rub, a widely used organic small molecular semiconductor in organic field-effect transistors and organic light-emitting diodes, was introduced into inverted perovskite solar cells as a hole transport layer to replace the conventional PEDOT:PSS. A high V_{oc} of 0.96 V, J_{sc} of 22.0 mA cm^{-2} , and PCE of 14.3% were achieved in our inverted planar heterostructure perovskite solar cells based on the rub hole transport layer due to the HOMO energy level matching between rub and MAPbI₃, large hole conductivity of rub, and large crystalline grain size of MAPbI₃ on rub. Our experimental results further demonstrate that the PEDOT:PSS/rub bilayer as the hole transport layer exhibits a higher PCE of 14.4% in the inverted perovskite solar cells due to the better film quality of rub and reduced recombination at the interface of rub/perovskite. In comparison with other organic hole conductors (e.g., PEDOT:PSS, spiro-OMeTAD, etc.), rub has bright prospects for applications in planar heterostructure perovskite solar cells due to its extremely low-cost and low-temperature treatment process. A future work is to reduce the exciton/carrier recombination at the rub/perovskite interface and enhance FF via improvement of the film quality of rub.
