# Dehalogenation of diatrizoate using nanoscale zero-valent iron: impacts of various parameters and assessment of aerobic biological post-treatment†

Pan-Pan He, Chuan-Shu He, Qi Liu and Yang Mu \*

This study investigated the feasibility of nanoscale zero-valent iron (nZVI) for reductive dehalogenation of iodinated contrast medium diatrizoate (DTA). The impacts of various parameters, including nZVI dosage, DTA concentration, solution pH, aging time of nZVI, the presence of natural organic matter, and the type of competitive anions, on the dehalogenation of DTA as well as the formation of its reductive product 5-diacetamidobenzoate (DABA) using nZVI were evaluated. Furthermore, an aerobic biological post-treatment was conducted to study the biodegradability of reductive products of DTA dehalogenation using nZVI. The results showed that dosing with 0.5 g L<sup>-1</sup> nZVI particles resulted in a rapid decrease in DTA concentration and a corresponding rise of the concentrations of DABA and I<sup>-</sup>. DTA dehalogenation in terms of its removal and DABA formation was enhanced with the increase in nZVI dosage but deteriorated when increasing solution pH. nZVI aging time had a negative impact on DTA dehalogenation. Natural organic matter at much low level could improve DTA dehalogenation, while had a negative influence at high concentrations. Contrary to sulfate, the presence of nitrate and phosphate strongly inhibited DTA removal using nZVI. The results also showed that the reductive product DABA could be degraded by aerobic biological post-treatment, suggesting DTA dehalogenation with nZVI may be a vital procedure for its biodegradability improvement and consequently complete removal.

## 1. Introduction

Iodinated contrast media (ICM) are widely used in hospitals for urinary tract imaging. A large number of ICM are used in tests for patients (>100 g per dose), and the annual world-wide consumption of ICM was reported as approximately 3.5 × 10<sup>6</sup> kg.<sup>1</sup> Due to their heavy use and high biochemical stability, increasing concentrations of ICM have been detected in hospital and domestic wastewater, treated wastewater effluent, surface water, groundwater, and even finished drinking water, whose concentration is up to μg L<sup>-1</sup>.<sup>2-6</sup> Although ICM are believed to be harmless, subtle effects of mixtures of ICM with their metabolites and other micropollutants are unknown and may exert unanticipated ecological or human health risks.<sup>7</sup>

Due to high oxidation resistance of the tri-iodinated aromatic ring structure, ICM have been reported to only lose their alkyl side chains by biological and chemical oxidation.<sup>7</sup> Alternatively, some reductive strategies have been developed for the removal of ICM from water, such as anaerobic biological

transformation,<sup>8</sup> dehalogenation through hydrogen with noble metal as the catalyst, and (bio)electrochemical reduction.<sup>7,9</sup> However, there are some shortcomings in those methods. Anaerobic biodegradation needs high activity microbial species, and long processing time. Other chemical methods suffer from high cost, which inhibits their wide application. Therefore, it's urgent to find an efficient and low-cost technique for the treatment of ICM from water.

Zero-valent iron (ZVI) is an active metal whose electric potential is -0.440 V. Iron releases electrons when it is oxidized, making it be able to remove a variety of pollutants.<sup>10</sup> It is noted that micro-scale ZVI powder has been successfully applied to treat iodine organic matters.<sup>11-13</sup> Compared to micro-scale ZVI, the nano-scale ZVI (nZVI) possesses greater surface activity to remove water pollutants effectively,<sup>14</sup> resulting from small particle size and sharp increase of specific surface area. Therefore, nZVI has been widely adopted to reductive removal of different pollutants such as chlorinated organic compounds,<sup>15,16</sup> nitro-aromatic compounds,<sup>17,18</sup> organic dyes<sup>19,20</sup> and heavy metals.<sup>21,22</sup> However, the utilization of nZVI to degrade ICM under anoxic conditions has seldom been investigated.

This study aimed at investigating the feasibility of nZVI for reductive dehalogenation of ICM from water, in which diatrizoate (DTA) was selected as the model ICM. The impacts of various parameters, including nZVI dosage, diatrizoate

concentration, solution pH, aging time of nZVI, the presence of natural organic matter (NOM), and type of competitive anions, on DTA dehalogenation using nZVI were evaluated. Furthermore, an aerobic post-treatment was conducted to study the biodegradability of reductive products of DTA dehalogenation using nZVI.

## 2. Materials and methods

### 2.1 Materials

Sodium diatrizoate ( $\geq 98\%$  purity) and its reductive product 5-diacetamidobenzoate (DABA,  $\geq 98\%$  purity) were purchased from Aladdin Industry Company (China) and Chem-Bridge Company (China), respectively. Humic acid was obtained from Sigma-Aldrich Company (Switzerland), and other chemicals including  $\text{NaBH}_4$ ,  $\text{FeCl}_3$ ,  $\text{NaCl}$ ,  $\text{NaNO}_3$ ,  $\text{Na}_2\text{SO}_4$ ,  $\text{HCl}$ ,  $\text{NaOH}$ , ethanol and riboflavin were purchased from Sinopharm Chemical Reagent Ltd (China). High purity of compressed  $\text{N}_2$  was obtained from Shangyuan Gas Products Co. (Nanjing, China). All the chemicals were used as receipt except for that humic acid was purified according to a previous method.<sup>23</sup>

### 2.2 Synthesis and characterization of nZVI

The nZVI particles were synthesized by using the liquid-phase reduction method.<sup>24</sup> Briefly, 19.32 g  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$  was dissolved into 200 mL 30% ethanol solution, following with  $\text{N}_2$  purge for 20 min. The reducing solution was prepared with 24.37 g  $\text{NaBH}_4$  dissolved into 400 mL deionized water. After that, the reducing solution was added into the ferric solution on a mechanical stirrer with the speed of 300 rpm. The drop rate of reducing solution was controlled at 60–70 drops per min. The mixture was left to stir for another 30 min after the addition of  $\text{NaBH}_4$  solution was completed. Centrifugation was used to separate the liquid phase solution and the solid black particles. The solid black particles were washed three times with deionized water and ethanol, respectively, and then dried in a vacuum oven overnight at 65 °C. The nZVI products were stored in an anaerobic operation box (Shellab, Bactron EZ, USA) containing 5%  $\text{H}_2$ , 5%  $\text{CO}_2$  and 90%  $\text{N}_2$  to avoid oxygen exposure.

The morphology of the synthesized nZVI nanoparticles (NPs) was examined using a transmission electron microscope (TEM) with a JED-2300T (JEM-2011, JEOL Ltd., Japan) and a ZEISS GEMINISEM 500 scan electron microscope (SEM) (EHT = 3.00 kV, Mag = 30.00k $\times$ , WD = 6.00 mm, JSM-6700F, JEOL Ltd., Japan). The freshly prepared nZVI samples were dispersed in ethanol by ultrasonic before TEM and SEM tests. X-ray diffraction (XRD) analysis of nZVI particles was performed by using a Japan Rigaku TTR-III X-ray diffractometer at 40 kV and 100 mA with a  $\text{Cu K}\alpha$  ( $\lambda = 1.54178$ ) radiation source. Iron nanoparticles were scanned from 10° to 80° at 0.020° per step and 8°  $\text{min}^{-1}$ . Also, Fourier Transform Infrared (FTIR) spectrometer was used to examine the nZVI before and after the dehalogenation reaction (Nicolet 8700, Thermo Nicolet, USA).

### 2.3 DTA dehalogenation experiments

In the typical degradation experiments, 0.5 mL of 6 mM DTA solution was added into a 150 mL serum bottle containing 100 mL deionized water with pH at 7.0, then was purged with nitrogen for 15 min. Further, 0.05 g nZVI was added into the solution in the anaerobic operation box, and then the bottle was immediately sealed tightly with rubber stoppers and aluminum caps following with continuous shaking with 150 rpm at 25 °C for 120 h by using a bath shaker.

The effects of various parameters on DTA dehalogenation were investigated, including nZVI dosage, DTA concentration, pH, nZVI aging time, the presence of NOM (riboflavin and humic acid), and competitive anions ( $\text{SO}_4^{2-}$ ,  $\text{PO}_4^{3-}$  and  $\text{NO}_3^-$ ). The experimental conditions are summarized in Table 1. The initial solution pH was adjusted using 2 M  $\text{HCl}$  or  $\text{NaOH}$ . Each experiment was carried out in duplicate.

### 2.4 Aerobic post treatment

An aerobic post-treatment was conducted at room temperature to test the biodegradable ability of the product from DTA dehalogenation in this study. After 96 h dehalogenation by nZVI with initial DTA concentration of 30  $\mu\text{M}$ , the solution was collected and then centrifuged to prepare basal medium for aerobic biological treatment. The composition of basal medium was as follows ( $\text{mg L}^{-1}$ ): glucose 1880,  $(\text{NH}_4)_2\text{SO}_4$  2830,  $\text{KH}_2\text{PO}_4$  132,  $\text{K}_2\text{HPO}_4 \cdot 3\text{H}_2\text{O}$  221,  $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$  250,  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$  200,  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$  200 and 1.0 mL trace element solution. The trace element solution contained ( $\text{mg L}^{-1}$ ):  $\text{H}_3\text{BO}_3$  50,  $\text{ZnCl}_2$  50,  $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$  30,  $\text{MnSO}_4 \cdot \text{H}_2\text{O}$  50,  $\text{Na}_2\text{Mo}_7\text{O}_{24} \cdot 2\text{H}_2\text{O}$  60,  $\text{AlCl}_3$  50,  $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$  50, and  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$  50.<sup>25</sup> 2 g  $\text{L}^{-1}$   $\text{NaHCO}_3$  was added as buffer solution. 10 g VSS per L (VSS: volatile total solids) of aerobic sludge from Wangtang municipal wastewater treatment plant (Hefei, China) was inoculated into a 440 mL serum bottle with basal medium to a final working volume of 250 mL. To exclude the possibility of sludge adsorption, the control experiments were conducted without oxygen. A pump was used to purge air into the solution to guarantee adequate oxygen during experiments. The dissolved oxygen (DO) in the solution was monitored with LDO101 dissolved oxygen probe (HACH, USA). Additionally, experiments with 30  $\mu\text{M}$  DTA in the basal medium were also conducted to investigate whether DTA could be degraded by the aerobic activated sludge. Each experiment was repeated twice.

### 2.5 Analysis and calculations

Samples were collected at selected time intervals by syringes and then filtered through a 0.45  $\mu\text{m}$  membrane for further analysis. The concentrations of DTA and DABA were analyzed using high performance liquid chromatography (Agilent 1260, USA) with an Agilent HC-C18 column (5  $\mu\text{m}$ , 4.6 mm  $\times$  250 mm). The mobile phase was a mixture of 0.1% formic acid–methanol (75 : 25, v/v) with flow rate of 1.0  $\text{mL min}^{-1}$  and the UV detector was set at 254 nm. Samples after 24 h dehalogenation reaction in the typical experiments were collected for the identification of intermediate products using liquid

Table 1 Summary of operational conditions for different experiments

Experiments	Operational conditions

chromatography electrospray ionisation tandem mass spectrometry (LC-ESI-MS) (LTQ-Orbitrap XL, ThermoFisher Co., USA), in which the chromatographic conditions are as same as those for DTA and DABA analysis, and other parameters are summarized in Table S1 of the ESI.† The concentrations of SO<sub>4</sub><sup>2-</sup> and PO<sub>4</sub><sup>3-</sup> were determined by ion chromatography (DIONEX ICS-1100, USA) equipped with an AS19 column and an electrical conductivity detector. The KOH effluent was used as mobile phase with concentration gradient ranging from 10 to 40 mM and 25 to 65 mM at 1 mL min<sup>-1</sup>, respectively. I<sup>-</sup> concentration was analyzed by using UV-vis spectrophotometer (Agilent Cary 60, USA) at 226 nm,<sup>26</sup> while Fe<sup>2+</sup> concentration was determined with phenanthroline method at 510 nm.<sup>27</sup> The concentrations of NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> were measured with UV-vis spectrophotometer (Agilent Cary 60, USA) at 220 and 697 nm by coordinating with salicylic acid and hypochlorous acid, respectively.<sup>27</sup>

The DTA removal efficiency (DRE, %) and the DABA formation efficiency (DFE, %) at time *t* (h) were determined using the following equations:

$$\text{DRE} = (C_{\text{DTA},0} - C_{\text{DTA},t})/C_{\text{DTA},0} \times 100$$

$$\text{DFE} = C_{\text{DABA},t}/C_{\text{DTA},0} \times 100$$

where  $C_{\text{DTA},0}$  (μM) is the initial DTA concentration,  $C_{\text{DTA},t}$  (μM) is the DTA concentration at reaction time *t* (h), and  $C_{\text{DABA},t}$  (μM) is the DABA concentration at reaction time *t*.

### 3. Results and discussion

#### 3.1 Typical DTA dehalogenation with nZVI

As shown in Fig. 1a, nZVI particles prepared in our study had a chain-like, core-shell structure and were nearly spherical with a size around 50 nm,<sup>28</sup> which was also demonstrated by the SEM image (Fig. 1b). The peak at 44.67° in Fig. 1c confirmed that Fe<sup>0</sup> was the majority of the particle component.<sup>28</sup> Fig. 2a illustrates the trend in concentrations of DTA, DABA and I<sup>-</sup> over time in typical DTA dehalogenation experiments using nZVI particles. Dosing with 0.5 g L<sup>-1</sup> nZVI particles resulted in a rapid decrease of DTA concentration and a corresponding rise of the concentrations of DABA and I<sup>-</sup>. The DTA removal efficiency reached to 100% within 24 h, while the DABA formation efficiency was only 39.6% in 24 h and it reached to 84.0% after 120 h reaction. In addition, it should be mentioned that DABA concentration still slowly increased with reaction time after DTA was completely removed (Fig. 2a). Moreover, the adsorption of DABA on nZVI was negligible, as shown in Fig. S3.† These results indicate that DTA dehalogenation by nZVI was fast while the DABA formation was the limiting step reaction. Therefore, we speculate that all

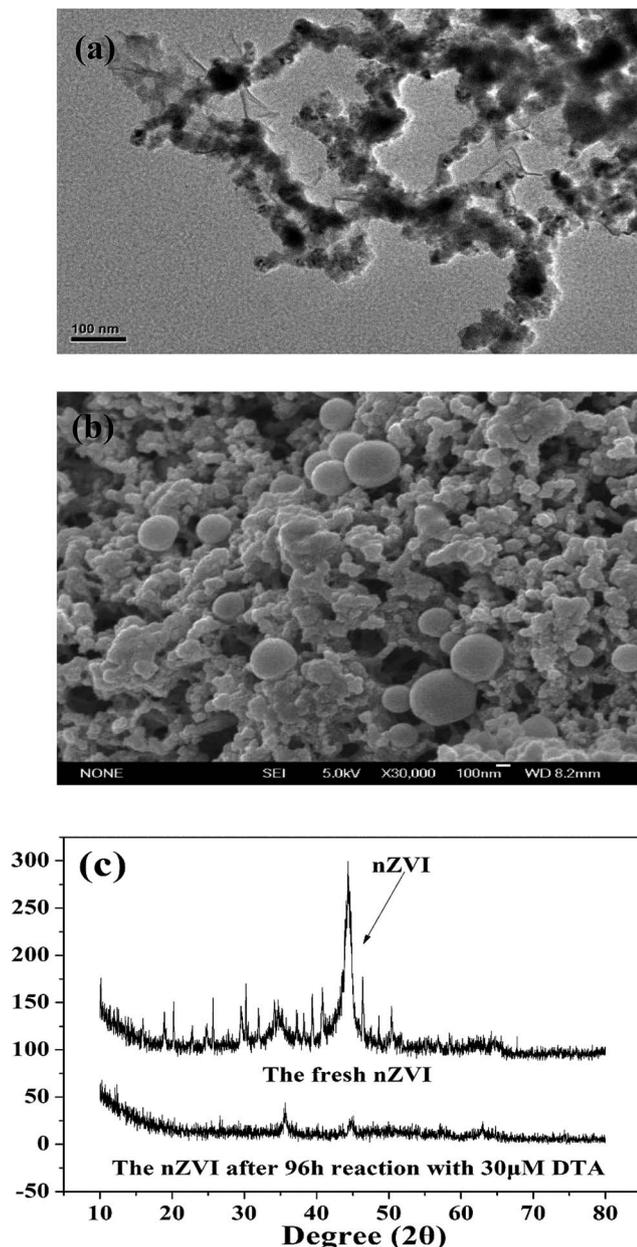

Fig. 1 Images of the synthesized nZVI particles: (a) TEM, (b) SEM and (c) XRD.

DTA could be completely reduced to DABA by nZVI but with much long reaction time at high pHs.

As illustrated in Fig. 2b, the reaction pH increased rapidly from 7.0 to 9.4 within 2 h because of the reaction between nZVI and  $\text{H}_2\text{O}$  or DTA with proton consumption.<sup>11</sup> After that, the solution pH changed slightly, properly due to the equilibrium for the  $\text{Fe}(\text{OH})_2/\text{H}_2\text{O}$  system ( $\text{pH} = 8.9$ ).<sup>29</sup> Fig. 1c shows that the crystal form of nZVI was totally destroyed after 96 h dehalogenation reaction. The nZVI surface passivation under high pH occurs easily, while DTA removal and DABA formation were continuous after 2 h in this study. Additionally, we also tested the reductive ability of  $\text{Fe}^{2+}$  and found that DTA concentration changed slightly regardless of  $\text{Fe}^{2+}$  concentration (Fig. 2c).

Thus, the possible contribution to DTA removal and DABA formation in this study may partially result from surface-bound  $\text{Fe}^{2+}$  and/or other reactive corrosion products like green rust. Several studies have reported that the green rust could dechlorinate different pollutants effectively.<sup>30,31</sup> Erbs *et al.* found that green rusts formed during corrosion of ZVI under nonacid conditions may considerably contribute to the total reduction of  $\text{CCl}_4$ .<sup>30</sup> Satapanajaru *et al.* reported that the green rusts provided a source of  $\text{Fe}(\text{II})$  and produced magnetite (and other oxide surfaces) that coordinated  $\text{Fe}(\text{II})$ , which then facilitated dechlorination.<sup>31</sup>

As shown in Fig. 2a,  $\text{I}^-$  concentration increased from 0 to  $77.46 \mu\text{M}$  within 96 h due to the dehalogenation of DTA in the typical experiments. Based on the mass balance calculation, the total detectable iodine concentration (*i.e.*,  $\text{I}^-$  concentration +  $3 \times C_{\text{DTA},t}$ ) decreased from 90 to  $53.78 \mu\text{M}$  and then increased to  $77.46 \mu\text{M}$  during reaction (Fig. 2d). The missing iodine was speculated to exist in the intermediate products with one or two iodine loss during DTA dehalogenation.<sup>8</sup> The results from LC-ESI-MS analysis confirmed the formation of intermediate products (DTA-2I, DTA-I) during DTA dehalogenation process, as shown in Fig. S1 and S2.† Since each DTA dehalogenation experiment was carried out under anaerobic conditions, it could be concluded that reductive transformation was majorly happened during DTA dehalogenation by nZVI in this study. The oxidative Fenton like reaction for DTA degradation would be negligible because this reaction need an aerobic condition. Recently, Stieber *et al.* investigated ICM removal by granular ZVI with a particle size of 0.125–3.000 mm in the presence of oxygen at acidic pH conditions,<sup>11</sup> and DTA only reduced by 60% in 8 h, indicating a slower removal rate compared to our study. Besides for reductive transformation by ZVI, they found that oxidative process were also responsible for the removal of ICM, which is due to the formation of hydrogen peroxide as an intermediate product for the oxidation of ZVI in aerobic water.

### 3.2 Effects of various parameters

**3.2.1 nZVI dosage.** The effect of nZVI dosage on DTA dehalogenation is shown in Fig. 3a and b. DTA was completely degraded in 24 h at different nZVI dosages, but both the removal rate and efficiency of DTA were merely affected by the dosage of nZVI in a range of  $0.1\text{--}1.0 \text{ g L}^{-1}$  (Fig. 3a). The DABA formation efficiency at 48 h was increased from 40.3% to 73.7% when nZVI dosage was increased from 0.1 to  $0.5 \text{ g L}^{-1}$ , and then changed slightly with the further increase to  $1.0 \text{ g L}^{-1}$  (Fig. 3b). These results further imply that DTA dehalogenation was fast by nZVI while DABA formation was the rate-limiting step. However, Li *et al.* found that higher nZVI dose resulted in the higher  $\text{Cr}(\text{VI})$  reduction rate for  $\text{Cr}(\text{VI})$  immobilization using nZVI particles.<sup>32</sup>

**3.2.2 DTA concentration.** The removal of DTA with nZVI as a function of initial DTA concentration was examined in the range of  $5\text{--}60 \mu\text{M}$ . The DTA could be degrade completely within 36 h in all batch experiments, while the amount of dehalogenated DTA increased with the increase in initial DTA concentration (Fig. 3c). Meanwhile, the amount of DABA generated increased with the increase in initial concentration of

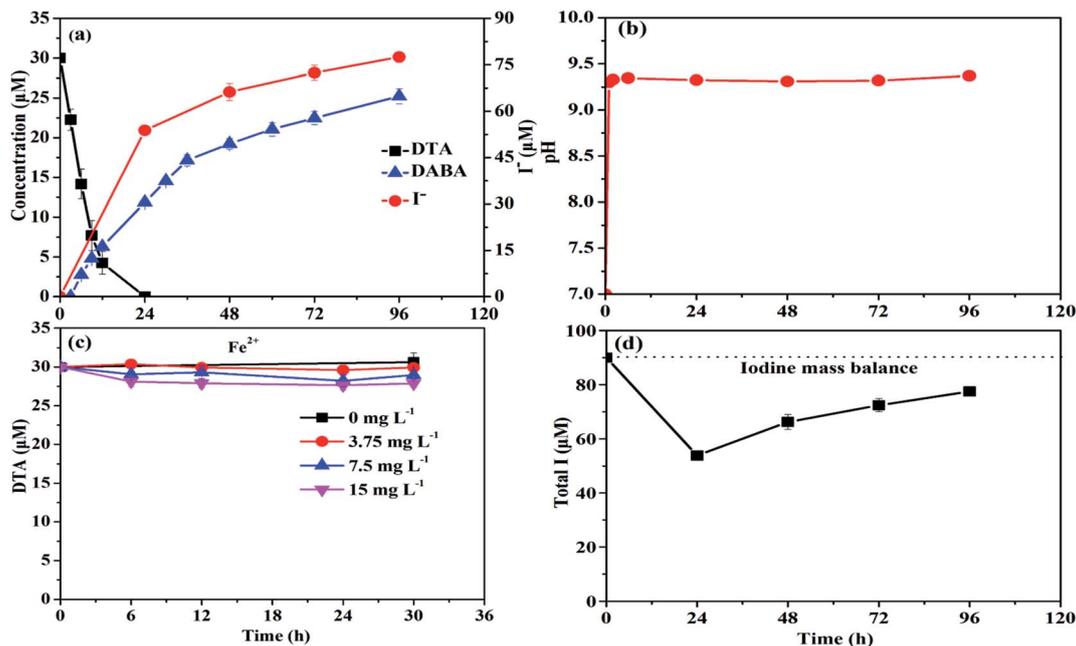

Fig. 2 Variations of (a) DTA removal, DABA formation and  $\text{I}^-$  release, (b) pH as a function of reaction time in typical dehalogenation experiments ( $30 \mu\text{M}$  DTA,  $0.5 \text{ g L}^{-1}$  nZVI, and pH at 7), and (c) DTA removal by  $\text{Fe}^{2+}$  at various concentrations, and (d) the total detectable I.

DTA, but the DABA formation efficiency was similar under different initial DTA concentrations, which reached to nearly 80% after 120 h reaction (Fig. 3d). A similar phenomenon was also observed for tetracycline removal using polyvinylpyrrolidone modified nZVI, where the amount of

tetracycline removed increased with the improvement of initial tetracycline concentration.<sup>33</sup>

**3.2.3 pH.** The removal of DTA as well as the generation of DABA was investigated as a function of initial solution pH from 3.0 to 9.0. As shown in Fig. 4a and b, solution pH had a significant impact on both the removal of DTA and the formation of

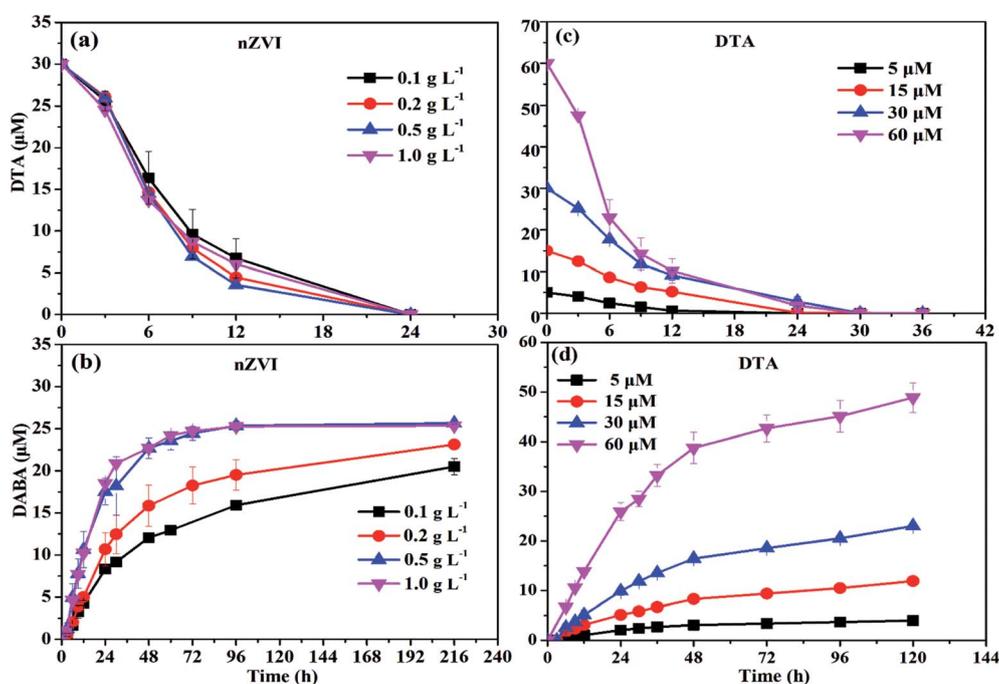

Fig. 3 Effect of nZVI dosage on (a) DTA removal and (b) DABA formation, and effect of DTA concentration on (c) DTA removal and (d) DABA formation.

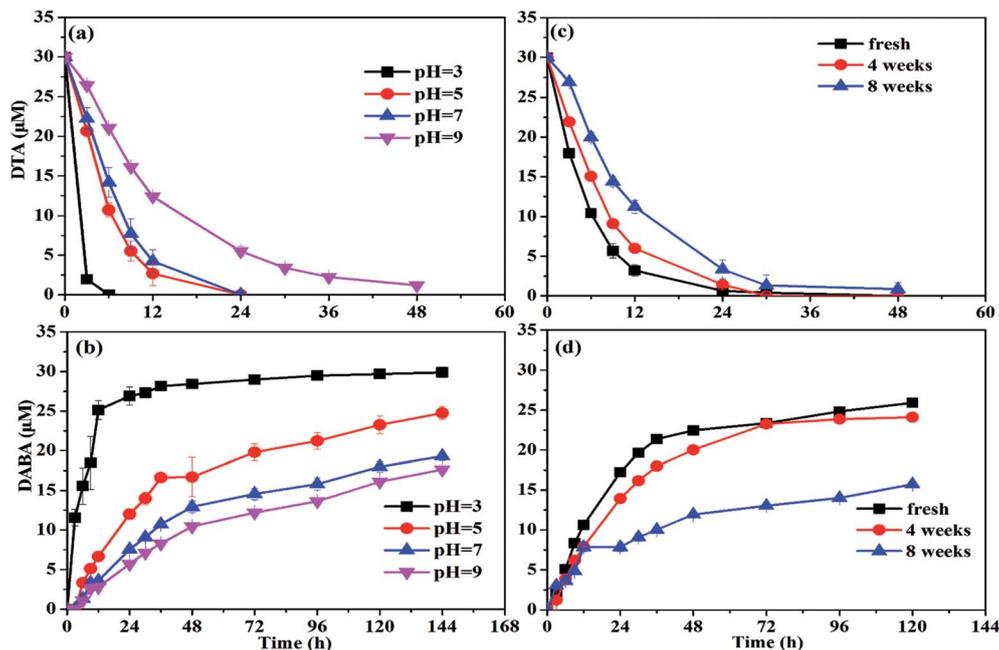

Fig. 4 Effect of pH on (a) DTA removal and (b) DABA formation, and effect of nZVI aging time on (c) DTA removal and (d) DABA formation.

DABA. When initial pH was increased from 3.0 to 9.0, the DTA removal efficiency at 9 h was reduced from 100% to 46.3%, and simultaneously the DABA formation efficiency at 24 h was decreased from 89.7% to 19.0%. pH is well known to affect rates of reactions with ZVI due to effects on iron corrosion, producing more corrosion at lower pH values and more passivation by mineral precipitation at higher pH values.<sup>34</sup> We found that the solution pH rapidly changed from 3.0, 5.0, 7.0 and 9.0 to 6.4, 7.5, 9.4 and 9.5, respectively, and then kept constantly.

Therefore, the deterioration of DTA removal as well as DABA generation at higher pHs could be attributed to the fact that the precipitation generated and wrapped the nZVI to inhibit the contact between nZVI and DTA.

**3.2.4 nZVI aging time.** The aggregation and shell transformation of nZVI particles with time could affect their reactivity and longevity.<sup>29</sup> Compared with fresh nZVI, the DTA removal efficiency at 12 h was decreased from 89.0% to 80.0% and 62.6% using nZVI with aging time at 4 and 8 weeks,

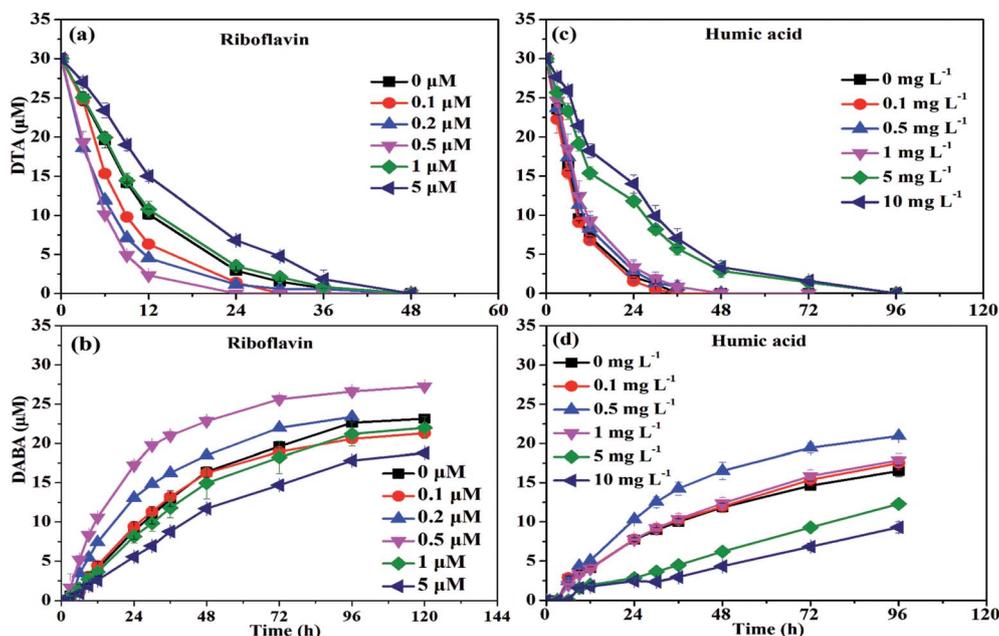

Fig. 5 DTA dehalogenation with nZVI in the presence of two different NOMs.

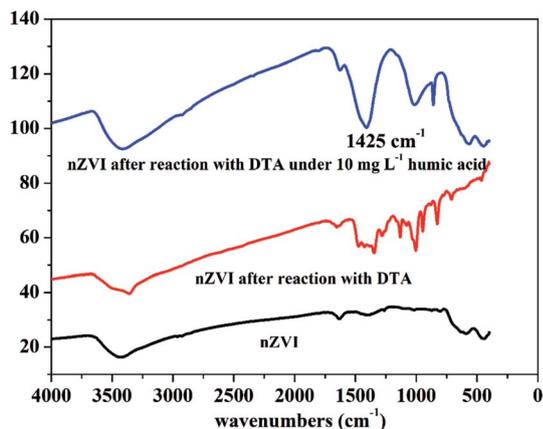

Fig. 6 FTIR images of nZVI before and after dehalogenation reaction in the presence or absence of humic acid.

respectively (Fig. 4c). Meanwhile, the DABA formation efficiency at 24 h was significantly reduced to 26.1% using nZVI with aging time at 8 weeks (Fig. 4d). We did not find the remarkable aggregation of nZVI particles with different aging times in this study. It was reported that the nZVI could transform into iron oxide particulates like FeO,<sup>35</sup> FeOOH,<sup>36</sup>  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>3</sub>O<sub>4</sub><sup>37</sup> to form the oxide shell on the surface of nZVI during aging and moreover the oxide shell increased with increasing aging time.<sup>29</sup> This might prevent the contact between nZVI and DTA and thus result in the poor dehalogenation performance.

To activate the aged nZVI and recover its reactivity, several methods can be effective, such as acid washing, H<sub>2</sub>-

pretreatment and ultrasound. After acid washing, the oxide layer on the surface of nZVI is able to be dissolved into solution and transformed into Fe<sup>2+</sup> or Fe<sup>3+</sup>. It involves the reconversion of oxidized iron compounds to iron chlorides, which can participate again as a precursor in a regenerating synthesis process with NaBH<sub>4</sub> reductant to produce nZVI.<sup>38</sup> The H<sub>2</sub>-pretreatment method offered several advantages over the acid-washing method practically without wastewater or sludge generation. Liou *et al.* employed hydrogen gas at 400 °C to activate the ZVI surface to improve nitrate removal by ZVI and they found that the lag period of nitrate removal by H<sub>2</sub>-pretreated ZVI disappeared and the first-order reaction rate constant was increased by 4.7 times compared with the non-pretreated ZVI.<sup>39</sup> The ultrasound method serves to increase the active iron surface, improve reaction rates, and increase the concentration of terminal by-products. Geiger *et al.* showed the kinetic improvement caused by ultra-sound pretreatment and illustrated that ultrasound could clear the iron surfaces of debris and thus increase the surface area up to 169%.<sup>40</sup>

**3.2.5 The presence of NOM.** NOM, widespread in the environment where nZVI technologies are most applicable, is an important factor for controlling the degradation of contaminants.<sup>41</sup> The effect of two common NOMs, *i.e.*, riboflavin and humic acid, on DTA removal with nZVI was evaluated in this study. As shown in Fig. 5, both of them showed a similar consequence for DTA dehalogenation. The rates of both DTA removal and DABA generation increased as riboflavin concentration was increased from 0 to 0.5  $\mu$ M, while they reduced when riboflavin concentration further increased from 0.5 to 5  $\mu$ M. Similarly, the DABA formation efficiency increased from 55.0%

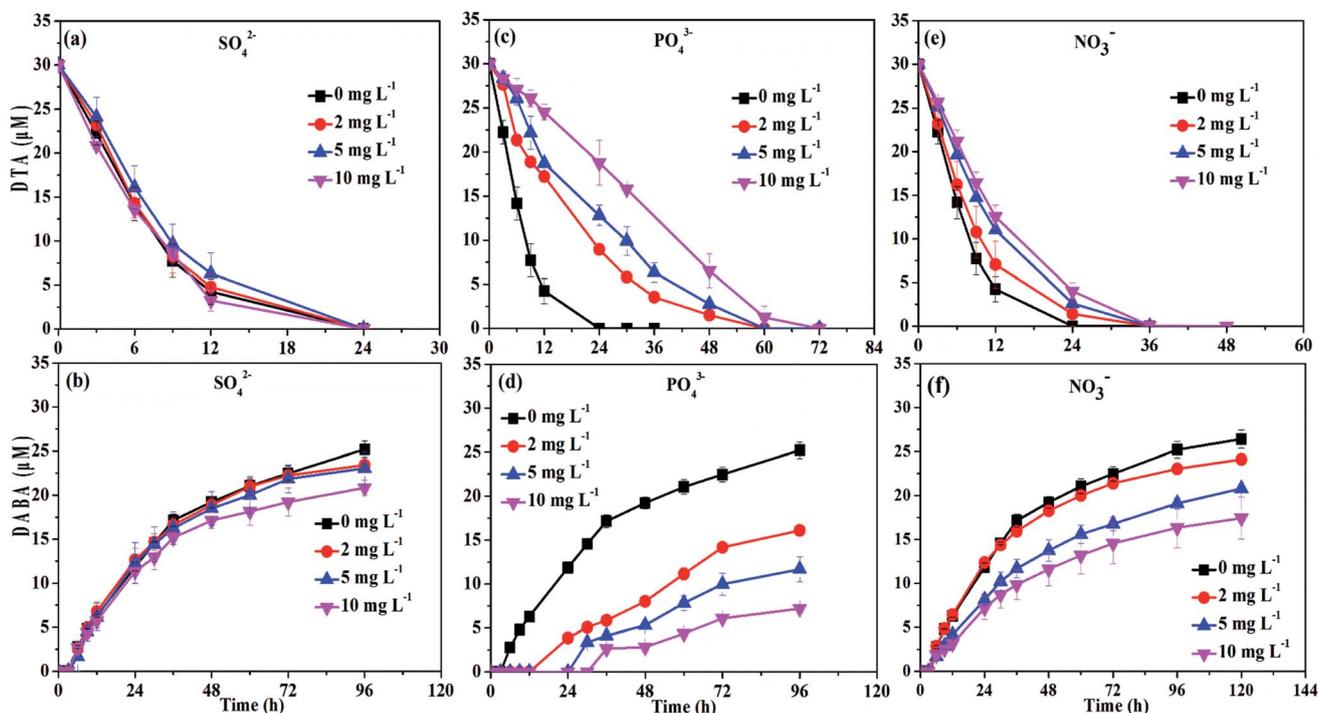

Fig. 7 DTA dehalogenation with nZVI in the presence of different anions ( $\text{SO}_4^{2-}$ ,  $\text{PO}_4^{3-}$ , and  $\text{NO}_3^-$ ).

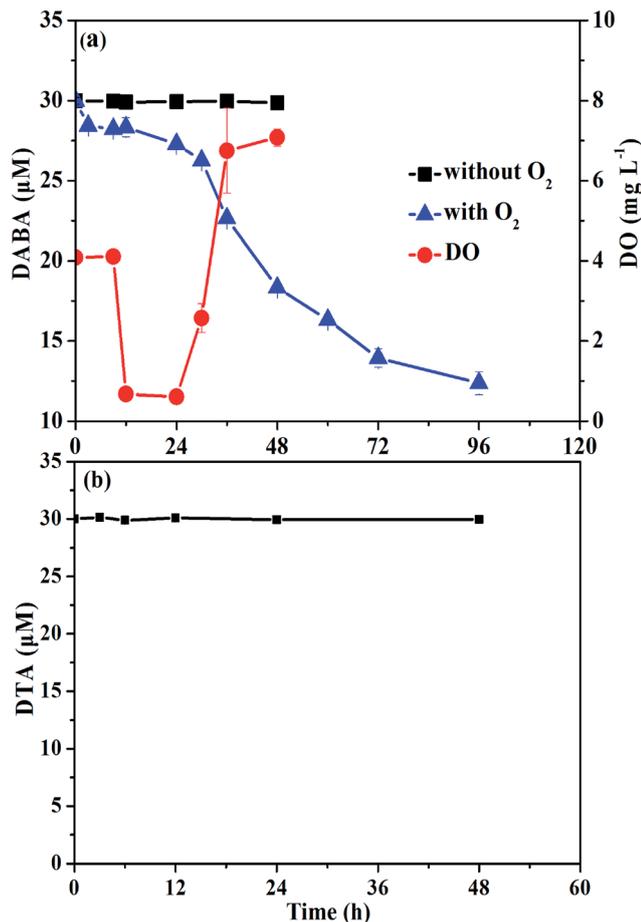

Fig. 8 Concentration changes of DTA, DABA and DO during aerobic biological post-treatment.

to 69.8% after 96 h when the concentration of humic acid was increased from 0 to 0.5 mg L<sup>-1</sup>, and then reduced to 31.0% with a further increase in humic acid concentration to 10 mg L<sup>-1</sup> (Fig. 5d).

At low concentrations, several studies have found that NOM was able to act as the electron shuttle to rapidly transfer electrons, leading to enhanced reductive degradation of contaminants.<sup>42</sup> For instance, Kim *et al.* observed that the degradation rate of NO<sub>3</sub><sup>-</sup> by nZVI was accelerated in the presence of 6.25–100 mg L<sup>-1</sup> humic acid, and they suggested that quinone moieties (*e.g.*, *p*-hydroquinone, lawsone, and 9,10-anthraquinone-2,6-disulfonate (AQDS)) in humic acid played a pivotal role in enhancing degradation of NO<sub>3</sub><sup>-</sup> by nZVI.<sup>42</sup> On the contrary, in the presence of high concentration of NOM, adsorption of NOM onto reaction sites on the surface of iron phases would play a major role in inhibiting the reductive degradation of pollutants by nZVI. Adsorption of NOM can compete with contaminants in ways which can decelerate the kinetics of contaminant degradation.<sup>42,43</sup> The FTIR images further proved this phenomenon. As shown in Fig. 6, a characteristic peak at 1425 cm<sup>-1</sup>, belongs to -CH deformation of -CH<sub>3</sub> and -CH bending of CH<sub>2</sub> (ref. 44), was found in the presence of

10 mg L<sup>-1</sup> humic acid, strongly suggesting the adsorption of humic acid on the surface of nZVI.<sup>36</sup>

**3.2.6 Competitive anions.** The effects of different anions (SO<sub>4</sub><sup>2-</sup>, PO<sub>4</sub><sup>3-</sup> and NO<sub>3</sub><sup>-</sup>) on DTA dehalogenation using nZVI are shown in Fig. 7. Sulfate had an insignificant influence on DTA dehalogenation in terms of DTA removal and DABA formation (Fig. 7a and b), while both PO<sub>4</sub><sup>3-</sup> and NO<sub>3</sub><sup>-</sup> showed passive impacts.

The DTA removal efficiency at 24 h reduced from 100% to 37.4% when PO<sub>4</sub><sup>3-</sup> concentration was improved from 0 to 10 mg L<sup>-1</sup>, and at the same time the DABA formation efficiency at 48 h decreased from 64.1% to 9.4% (Fig. 7c and d). The negative effect might be due to that PO<sub>4</sub><sup>3-</sup> is an inner-sphere complex-forming anion which could strongly sorb to mineral surfaces, thus hindering the sorption of DTA on the surface of nZVI particles. Indeed, we found that the PO<sub>4</sub><sup>3-</sup> in the solution completely disappeared after reaction. The disappearance of PO<sub>4</sub><sup>3-</sup> may result from precipitation with ferrous ion or coprecipitation with Fe(OH)<sub>2</sub> due to high pH.<sup>45</sup> Chen *et al.* also observed that PO<sub>4</sub><sup>3-</sup> had a negative effect on the removal of tetracycline with polyvinylpyrrolidone modified nZVI.<sup>33</sup>

Similarly, the rates of both DTA removal and DABA formation reduced when concentration of NO<sub>3</sub><sup>-</sup> were increased from 0 to 10 mg L<sup>-1</sup> (Fig. 7e and f). As shown in Fig. S4,† NO<sub>3</sub><sup>-</sup> was completely transformed into NH<sub>4</sub><sup>+</sup> by nZVI after 24 h reaction with initial NO<sub>3</sub><sup>-</sup> concentration of 10 mg L<sup>-1</sup>, and the removal efficiency at 12 h reached to 87.4%, suggesting that NO<sub>3</sub><sup>-</sup> removal was faster than DTA reduction by nZVI. This implies that NO<sub>3</sub><sup>-</sup> was able to compete with DTA for reactive sites and electrons of the nZVI, resulting in inhibition of DTA dehalogenation. Meanwhile, the reaction between NO<sub>3</sub><sup>-</sup> and nZVI could make the oxide-shell thicker, and the surface passivation become more seriously with the concentration of NO<sub>3</sub><sup>-</sup> increased.<sup>46</sup>

### 3.3 Performance of aerobic biological post-treatment

To test the biodegradability of reductive products of DTA dehalogenation using nZVI, aerobic biological post-treatment was conducted in this study. We first excluded the volatilization possibility of DABA even with O<sub>2</sub> supply (data not shown). As shown in Fig. 8, DABA concentration was unchanged without O<sub>2</sub> supply, suggesting insignificant adsorption of DABA onto sludge. In the presence of oxygen, the DABA removal efficiency was 58.8% after 96 h, indicating that aerobic sludge had a good degradation ability on DABA. The other transformation products including DTA-2I and DTA-I, which are present with much low concentrations, were not examined during aerobic degradation experiments. Meanwhile, the DO concentration declined in first 8 h and then increased to around 8 mg L<sup>-1</sup>, majorly due to the consumption of glucose in the solution. In addition, we also found that DTA couldn't be degraded by aerobic biological treatment (Fig. 8b). These results illustrated that DTA dehalogenation with nZVI would be a vital procedure for its biodegradability improvement and consequently complete removal.

## 4. Conclusions

The present study demonstrated that the nZVI could be effectively adopted for the dehalogenation of DTA. The DTA removal efficiency reached to 100% within 24 h in typical experiments with 0.5 g L<sup>-1</sup> nZVI particles. DTA dehalogenation in terms of its removal and DABA formation was enhanced with the increase in nZVI dosage but deteriorated when increasing solution pH. nZVI aging time had a negative impact on DTA dehalogenation. The presence of NOM at much low level could improve DTA dehalogenation, while negatively affected DTA removal at high concentrations. Contrary to sulfate, both nitrate and phosphate ions strongly inhibited DTA removal with nZVI. The results also showed that DABA could be degraded by aerobic biological post-treatment, suggesting DTA dehalogenation with nZVI may be a vital procedure for its biodegradability improvement and consequently complete removal.
