Fabrication of p-ZnO:Na/n-ZnO:Na homojunction by surface pulsed laser irradiation

Xiaopeng Yang, Xiang Xu, Feng Liu, Liqiang Zhang, Ziwu Ji, Qifeng Chen and Bingqiang Cao*

An ingenious method of preparation of ZnO homojunctions for on-chip integration purposes is proposed, by local multiple pulse laser irradiating (MPLI) ZnO:Na film (NZO). The importance of this method lies in realization of p- and n-ZnO using only one kind of dopant (Na element) with a single layer of NZO film. The p-NZO as prepared by pulsed laser deposition (PLD) easily changes to n type after a couple of hours. However, more than ~150 times MPLI with laser fluence of 60 mJ cm⁻² can be used to efficiently control the Na dopants to occupy the substitutional (NaZn) sites to realize a more stable p-NZO. The low temperature (6 K) PL spectra of the p-NZO at excitation power of 6 mW and the first principle calculation show that the acceptor energy level is ~161 meV. The current–voltage (I–V) curve of the p–n NZO homojunction fabricated by local MPLI shows good rectifying behavior, with turn on voltage at ~2.47 V under forward bias voltage and reverse breakdown voltage bias ~11.22 V. This convenient p–n junction technique could be used to simplify and improve controllability and accuracy of fabrication of microchip electronic devices.

Introduction

Solid state electronics have attained a level of sophistication and economic importance far beyond the expectations of their inventors. There is continuous demand for better performing devices at lower cost and using novel fabrication techniques. A vital component of solid state electronics is semiconductor p–n junctions. These can be used as rectifiers as one part of DC power supplies and restorers in bracing systems, detector circuits, switches in advanced rationale circuits, and so on. Current fabrication techniques of p–n junctions mainly comprise alloying or fusion, solid or gaseous diffusion, ion implantation, epitaxial growth, and point contact. However, almost all these mature technologies require complex processes to realize photolithography techniques, epitaxial growth, or high ambient temperatures to achieve material fusion and impurity diffusion, and it is particularly hard to realize precise positioning. These represent obstacles to microchip application of semiconductor junctions for separating the semiconductor doping process from other processes. In recent years, laser irradiation (LI), also called laser annealing (LA), has received much research interest in formation of ultrashallow junctions essential in semiconductor technology. LI typically melts the surface region of the implanted substrate and causes the dopant to be distributed uniformly, and there is a high concentration of dopant incorporation, exceeding the solid solubility because of solute trapping under the highly nonequilibrium recrystallization process. Currently, however, the LI technique is used only as an annealing process; it has not been used as a fabrication method of semiconductor p–n junctions.

The present study proposes an ingenious method for preparation of homojunctions for on-chip integration purposes by multiple pulse laser irradiating (MPLI) ZnO:Na film (NZO) to control Na dopant to occupy the substitutional (NaZn) or interstic (Na₃) sites to realize p/n-NZO. This novel technique could be useful for simplifying the working process and improving controllability and accuracy in microchip electronic device fabrication.

Experimental

First, NZO film of thickness ~2.4 µm was deposited by pulsed laser deposition (PLD) technique on glass substrates at a temperature of 550 °C and O₂ pressure of 40 Pa by ablasting ZnO₉₅Na₉₅O ceramic targets. The pulsed KrF eximer laser was employed as an ablation source. The distance from target to substrate and the growth duration were 5 cm and 1 h, respectively. Prior to the deposition, the base pressure of the vacuum chamber was evacuated to ~1.1 × 10⁻³ Pa. Then the NZO was repeatedly irradiated by pulse laser. The irradiation spot was oval shaped, with long and minor axes of ~8 and ~3.5 mm, respectively.
Before and after the MPLI, field emission scanning electron microscopy (SEM) was used to determine the thickness of NZO film via cross-section; top SEM imaging was used to determine changes in surface structure. Electrical resistivity, Hall mobility, and carrier concentration were measured by Hall effect and van der Pauw methods. Photoluminescence (PL) measurements were carried out at absolute temperature 6 K and excitation power 6 mW. The PL signals from the samples were dispersed using a Jobin-Yvon HR 320 monochromator and detected by a thermo-electrical cooled Sy-napse CCD detector. A power 6 mW. The PL signals from the samples were dispersed using a Jobin-Yvon HR 320 monochromator and detected by a thermo-electrical cooled Sy-napse CCD detector. A

Results and discussion

Fig. 1(a) shows the laser beam path diagram of the MPLI device. The KrF excimer laser (Coherent Inc. USA) has laser pulse duration and emitted wavelength of 25 ns and 248 nm, respectively. The processing parameters (i.e., laser power, laser spot size, and pulse frequency) require careful control to provide an appropriate temperature field on the sample surface. The laser beams are emitted horizontally from the KrF laser source and reflected downward by a reflection. The fluence of the laser spot on the NZO film can be easily adjusted by changing the value of L. Fig. 1(b) shows the thickness changes of the NZO film with different numbers of pulsed laser radiation (PLI) in atmospheric atmosphere at room temperature. Here, the laser fluence was adjusted to 60 mJ cm\(^{-2}\) and the frequency was set to 5 Hz. After MPLI, the thickness of the NZO was reduced by the laser ablation effect, as the surface temperature increases with increasing number of pulses.\(^{14}\) The average reduction rates of the A, B and C zones were 6.0, 1.375, and 3.65 nm per pulse, respectively. The film surface temperature can be expressed as\(^{12}\)

\[
T \propto \eta \frac{p}{Lr} \exp \left( \frac{L_f}{a} \right)
\]  

(1)

where \(p\) is the mean power of the laser beam, \(L_f\) the film thickness, \(r\) the laser beam radius, \(\alpha\) the thermal diffusivity, and \(\eta\) the scaling factor determined by the mixing ratio \((m)\) of ZnO single crystal grain with atmospheric air. The \(\eta\) values for rough and smooth surfaces are greater and less than 1, respectively.\(^{14}\) The \(p, r, \) and \(\alpha\) are considered as constants here. Based on eqn (1), the surface of the as-prepared NZO (a-NZO) shown in Fig. 2(a) was rougher than the laser-irradiated surfaces shown in Fig. 2(b)–(f). Thus, the related \(\eta\) should be greater than 1, leading to a higher temperature, corresponding to zone A, with reduction rate higher than in zone B. For zone C, the \(L_f\) is small enough to make the temperature rise sharply, resulting in the fastest thickness reduction rate of 3.65 nm per pulse.

Fig. 2 shows SEM images of the NZO surface morphologies with different PLI times. Fig. 2(a), the a-NZO, shows an uneven surface, subsidence holes, and nonuniform crystal grain size, leading to \(\eta\) greater than 1.\(^{14}\) Fig. 2(b)–(f) show the laser-irradiated NZO with MPLI (m-NZO) 150, 250, 350, 450, and 650 times, respectively. The increasing numbers of pulses of laser irradiation cause the film surface to become flatter, as seen in Fig. 2(b)–(e). Increasing the MPLI up to 650 times results in NZO with extreme smooth and uniform crystal grain without crystal burrs (Fig. 2(f)). This is attributed to the high temperature, causing the ZnO crystal grains to melt down and recrystallize.\(^{15}\) The diameter of a crystal grain is \(~250\) nm, as

Fig. 2 SEM images of the NZO film. (a) NZO; (b), (c), (d), (e), and (f) m-NZO with MPLI for 150, 250, 350, 450, and 650 times, respectively.
determined by the substrate’s thermal conductivity, where higher conductivity gives larger final NZO crystal size.25

Fig. 3 shows the XRD patterns of a-NZO and m-NZO with MPLI of 150, 250, 350, and 650, respectively. Only the XRD peak corresponding to wurtzite ZnO (002) plane is seen, revealing the high crystallinity and c-axis preferential orientation of the NZO films.26 The mean crystallite size can be calculated using the Scherrer equation with full width at half-maximum (FWHM) of the (002) peak. This gives mean crystallite sizes of a-NZO, and m-NZO with 150, 250, 350, and 650 times MPLI of 12.790, 15.267, 15.055, 16.102, and 16.420 nm, respectively. Thus, the MPLI process increases the crystallite size and improves crystal quality, via the previously mentioned process of crystal grain meltdown and recrystallization.

Fig. 4(a) shows the carrier concentration and Hall mobility as a function of standing time of NZO at room temperature. This indicates that the a-NZO is p type; however, its hole concentration drops from $5.06 \times 10^{19}$ to $9.15 \times 10^{17}$ cm$^{-3}$ within 50 minutes without any other treatment than the Hall testing. It then changes to n type within the next 50 minutes. Meanwhile, its carrier (electron) concentration increases up to $3.10 \times 10^{19}$ cm$^{-3}$ and the Hall mobility to 6.68 cm$^2$ V$^{-1}$ s$^{-1}$. The above mentioned phenomenon demonstrates the unstable p type electrical property of the a-NZO.27 In fact, there is a high energy barrier (3.4 eV) for NaZn transformation to Na$_i$, which is much higher than that (1.56 eV) of Na$_i$ to transform to a substitutional site.28 That is to say, NaZn is stable. Therefore, it is presumed that the initial p type conductivity of the a-NZO results from unstable p type defects rather than NaZn. When the NZO is annealed by MPLI for 150, 250, and 350 times, corresponding to points A, B, and C in Fig. 4(a), the temperature increases on the NZO surface. Meanwhile, the temperature decreases by ~49% of the peak temperature ($T_{\text{peak}}$) of each pulse in 600 ns, after which the next laser pulse comes. It can be calculated that after 30 laser pulses, the $T_{\text{peak}}$ would be higher than 1224 K.29 This is fairly close to the melting point of NZO; therefore, recrystallization of NZO is expected. After 150 pulses at A point in Fig. 4(a), the NZO film has experienced 150 cycles of rapid temperature increase and decrease processes, which provide sufficient thermodynamic energy for Na dopant to overcome the barrier energy from interstice site to substitutional site. The film then converts back to p type, as shown by the A, B, and C points. The hole concentration and Hall mobility reach up to $2.53 \times 10^{19}$ cm$^{-3}$ and 9.43 cm$^2$ V$^{-1}$ s$^{-1}$, respectively, at C point. That is to say, the Hall mobility is better than that of the a-NZO, resulting in improved crystallographic quality after laser annealing treatment. After 5 days, the hole concentration and Hall mobility are maintained at $1.62 \times 10^{19}$ cm$^{-3}$ and 6.97 cm$^2$ V$^{-1}$ s$^{-1}$. This demonstrates that the p type m-NZO has improved stability, which may arise from formation of Na$_{2z}$N. Fig. 4(b) shows the carrier concentration and Hall mobility of the m-NZO as a function of magnetic field intensity from 2 to 12 kG. It demonstrates good p type stability at different magnetic field intensities.

To characterize the optical properties of the NZO, PL was carried out at room temperature and low temperature (Fig. 5). Fig. 5(a) shows the normalized PL spectra at room temperature of a-NZO and m-NZO with MPLI for 0, 150, 250, and 350, and 650 times. All lines exhibit a dominant near-band-edge (NBE) emission, which is identified as the recombination of free exciton (FX).30 The strong NBE emission and negligible deep-
level emission indicate that the obtained ZnO film is of high optical quality, which is suitable for application in electronic devices, while a wide deep-level emission (around 510 nm) related to the oxygen vacancies (VO) or intestinal zinc (Zni) is observed. As acting as donor will compensate the acceptor, the efficiency of Na doping is therefore reduced. In other words, more efficient p-type NZO film could be obtained by restraining the density of wide deep-level defects. It is noted that increasing the number of MPLI times corresponds to a weakening in the density of wide deep-level defects. It is noted that increasing the number of MPLI times corresponds to a weakening in the density of wide deep-level defects. It is noted that increasing the number of MPLI times corresponds to a weakening in the density of wide deep-level defects. It is noted that increasing the number of MPLI times corresponds to a weakening in the density of wide deep-level defects. It is noted that increasing the number of MPLI times corresponds to a weakening in the density of wide deep-level defects. It is noted that increasing the number of MPLI times corresponds to a weakening in the density of wide deep-level defects.

The room temperature current–voltage (I–V) curves of the p/n-NZO homojunction are shown in Fig. 7(a). Good rectifying behavior of the junction is observed from the I–V characteristics. Its turn on voltage appears at ~2.47 V under forward bias voltage and the reverse breakdown voltage bias is ~1.22 V. The inset Ic shows a photo of the p/n-NZO homojunction on a glass substrate with a laser ablated spot. The insets Ic and Ic demonstrate good ohmic behavior of the contact between A–B and C–D points, which confirms that the rectification arises from the NZO homojunction between A and C points. Fig. 7(b) shows the band structure of the p/n-NZO homojunction. VB and VD are the valence band and contact potential difference or be ~161 meV, in good agreement with the calculation data 165 meV in Fig. 6(d). It is worth noting that the DAPs peak of the a-NZO disappeared after 5 days; this was proved to be n type by Hall Effect testing. This further corroborates that the P2 should be assigned to DAPs. When the a-NZO turned into n type after 5 days, the P2 disappeared. This may be caused by disappearance of the acceptor level. Meanwhile, the disappearance of the acceptor level results in expansion of the band gap, which may be the cause of the blue shift of P1. These results offer further proof that the P2 is related to acceptor Na2zn.

Fig. 6(a)–(f) shows the geometry optimized models and corresponding band structures of NZO crystal. The Na atoms are located at substitutional, tetrahedral interstice (Naai), and tetrahedral interstice (Naio) sites, respectively, shown in Fig. 6(a)–(c). The position of the Fermi-level in the band structures indicates that ZnO:Naai is p type and ZnO:Naio is n type, see Fig. 6(d)–(f). That is to say, p and n-ZnO could be obtained simply by doping Na elements, which gives theoretical support to the present work. The band gap energies are calculated to be 0.757, 0.796, and 0.789 eV for ZnO:Na2zn, ZnO:Naai, and ZnO:Naio, respectively. These values are underestimated compared with experimental data, which is a well-known artifact of traditional density functional theory (DFT). The Ea value from the first principle result is 165 meV, in good agreement with the experiment result of 161 meV from eqn (2).

The room temperature current–voltage (I–V) curves of the p/n-NZO homojunction are shown in Fig. 7(a). Good rectifying behavior of the junction is observed from the I–V characteristics. Its turn on voltage appears at ~2.47 V under forward bias voltage and the reverse breakdown voltage bias is ~1.22 V. The inset Ic shows a photo of the p/n-NZO homojunction on a glass substrate with a laser ablated spot. The insets Ic and Ic demonstrate good ohmic behavior of the contact between A–B and C–D points, which confirms that the rectification arises from the NZO homojunction between A and C points. Fig. 7(b) shows the band structure of the p/n-NZO homojunction. VB and VD are the valence band and contact potential difference or
threshold voltage. The $V_D$ of thermal equilibrium $p$-$n$ junction can be expressed as:

$$V_D = \frac{k_b T}{q} \ln \frac{N_D N_A}{n_i^2}$$

Here, $k_b$ denotes the Boltzmann constant, $T$ is the room temperature 300 K, $n_i$ is the intrinsic carrier concentration of ZnO ($\sim 1 \times 10^{17}$ cm$^{-3}$), $N_D$ is the donor concentration of the $n$-NZO of the homojunction ($3.1 \times 10^{19}$ cm$^{-3}$), and $N_A$ is the acceptor concentration of the $n$-NZO of the homojunction ($2.53 \times 10^{19}$ cm$^{-3}$). Thus, a $V_D$ value of 1.49 V is obtained, and the contact potential barrier height $\phi (=qV_D)$ for electron or hole is 2.385 eV. It is known that $V_D$ and $V_p$ are the sum of $V_n$ and $V_p$, and $V_n$ and $V_p$ are the voltages of the space charge region of $n$/$p$ zone of the $p$-$n$ junction, respectively.

$$V_{n/p} = \frac{k_b T}{q} \ln \frac{N_{D/A}}{n_i}$$

Thus, $V_n$ and $V_p$ are 0.748 and 0.743 V, respectively. The $V_D$ and $V_p$ should be 1.197 and 1.189 eV. It is also noted that the turn on voltage (2.47 V) based on the $I$-$V$ curve is far bigger than $V_D$ (1.49 V). This may be caused by the high resistance layer generated from the MPLI process in the interface of $n$- and $p$-NZA.

Conclusions

In summary, $p$/$n$-NZO homojunctions were prepared for on-chip integration purposes using a MPLI technique. The homojunction contains only Na dopants to realize $p$/$n$ type conductivity of the ZnO film. The MPLI process can reduce the film thickness at $\sim 1.375$ nm per pulse and improve the crystallinity by high temperature recrystallization. Meanwhile, it can also cause the Na dopants to occupy the substitutional sites of Zn to obtain more stable $p$ type $m$-NZO than the $n$-NZO. The hole concentration and Hall mobility of the $m$-NZO are up to 2.53 $\times$ $10^{19}$ cm$^{-3}$ and 9.43 cm$^2$ V$^{-1}$ s$^{-1}$, respectively. The low temperature PL spectra at excitation power of 6 mW and the first principle calculation show that the acceptor energy level is $\sim$161 meV. The $I$-$V$ curve of the $p$-$n$ NZO homojunction shows good rectifying behavior, with a turn on voltage of $\sim$2.47 V under forward bias voltage and the reverse breakdown voltage bias $\sim$11.22 V. This convenient technique could be used in simplifying and improving controllability and accuracy in fabrication of microchip electronic devices.
