Multi-type quantum dots photo-induced doping enhanced graphene/semiconductor solar cell

Jianghong Wu, Sirui Feng, Zhiqian Wu, Yanghua Lu and Shisheng Lin

1. Introduction

Photovoltaics is a promising technology for transferring clean, abundant, renewable sunlight energy into electrical power on a large scale, meeting a significant part of the increasing worldwide energy demand. Therefore, highly efficient solar cells are sharply demanded for human society. Indeed, many approaches have been reported to realize solar devices with better performance. Some novel materials with extraordinary electrical and optical properties including perovskite materials, carbon materials, and organic materials have been investigated for use in highly efficient solar cells. However, the stability of perovskite solar cells is an unsolved scientific problem and the PCE of ordinary organic solar cells is unsatisfactory. Distinct from a traditional PN junction, some novel approaches have been reported to realize solar devices with better performance. The properties of two-dimensional optoelectronic devices based on graphene have profusely drawn the attention of scientific community, because graphene possesses a few outstanding electrical and optical properties, containing extraordinarily high carrier mobility, 2D constant absorption of visible light, micro-scale ballistic transport, abnormal quantum Hall effect, outstanding thermal conductivity and high mechanical strength. It has been reported that the electrical and optical properties of graphene can be easily adjusted by surface adsorption of foreign molecules, electrical gating, magnetic effects, and surface plasmons. Especially, there is a continuously rising interest in the photo-induced doping of graphene, which can improve the properties of two-dimensional optoelectronic devices based on graphene. As shown in Fig. 1(a), the valence and conduction bands of semiconductor clearly bend when graphene contacts with the semiconductor. Actually, the depletion layer of the semiconductor is close to the interface of heterojunction, namely the surface. Simultaneously, the screening length in graphene is around 0.6 nm and the van der waals bonding nature, so the Fermi level of graphene can be adjusted by photo-induced doping. For incident light, the ultraviolet and visible photons can penetrate into the graphene/semiconductor heterostructure for a long distance.
and the photo-induced carriers cannot effectively be collected by the Gr and semiconductor, respectively. Therefore, it can be attractive to absorb the ultraviolet and visible light just on the surface of Gr/semiconductor solar cells, which can effectively dope Gr and lift up the barrier height of the heterostructure, leading to an obvious improvement of light conversion efficiency. As a result, it is reasonable to design a more effective photo-induced doping layer of Gr for usage of high efficient Gr/semiconductor solar cells. We come to the idea of using semiconductor QDs with varies of band gap as the photo-induced doping source. As shown in Fig. 1(b), the solar spectrum with a lot minimal values because of gas molecular absorption such as oxygen and carbon dioxide in the atmosphere. Generally, the wavelength of maximal energy intensity is about 500 nm which is close to the absorption peak of InP QDs and the external quantum efficiency (EQE) of Gr/GaAs solar cell is smaller in the ultraviolet band.\(^{25}\) In view of above-mentioned reasons, a synergetic photo-induced doping to enhance Gr/GaAs heterostructure solar cell is present in this work, which can utilize incident light more effectively. As shown in Fig. 1(c), ZnO QDs can absorb ultraviolet light and InP QDs absorb visible light whose wavelength is particularly below 530 nm, respectively, generating excess holes injects into Gr. At the same time, thin film n-type GaAs can effectively absorb incident light whose wavelength is smaller than 874 nm. Therefore, under this cooperative photo-induced doping, the final PCE can be improved by 34.2% in this work.

### 2. Experimental section

#### 2.1. Fabrication of solar cell

Growth of monolayer Gr on copper foils was carried out at 1000 °C for 60 min with reaction source flux ratio of CH\(_3\) : H\(_2\) equaling to 5 : 1 by chemical vapor deposition (CVD) technique.\(^{26}\) Then polymethyl methacrylate (PMMA) working as the supporting layer was spun on Gr before removing the copper foil, and PMMA was subsequently removed by acetone for about 10 min. Trilayer Gr was obtained by multi-transferring monolayer Gr. The obtained ZnO and InP QDs were eventually diluted in ethanol and cyclohexane solvent, respectively. Thin film n-doped GaAs with a thickness of 2 µm was grown with metal organic CVD at 400 °C, at the same time, the doping concentration of the GaAs wafer was about 1 × 10\(^{18}\) cm\(^{-3}\). Then rear Au contact with a thickness of 60 nm was thermally evaporated on back surface of GaAs wafer. Native oxide on GaAs was removed by dipping the wafers into 10% wt dilute hydrochloric acid solution for 3 min. Surface passivation of GaAs was achieved by soaking treatment of mixed solution of ammonia sulfide and ammonia for 10 min. Gr was transferred onto the surface of ready GaAs, drying in air for half an hour and annealing for 10 min at 120 °C. Then PMMA at the surface of Gr was removed by acetone and silver paste was pasted onto Gr, followed by 120 °C/5 min post-anneal. Basing on the above operation, Gr/GaAs solar cell preliminarily came into being. Finally, the key manipulation was carried out as follows: InP QDs were spun on Gr at 4000 rpm for 60 s, and then the similar operation was performed again so as to introduce ZnO QDs to the surface of Gr.

#### 2.2. Characterization

InP and ZnO QDs were transferred to the carbon transmission electron microscopy (TEM) grid for morphology measurement using TEM (Tecnai F-30 operating at 300 kV). Trilayer Gr with and without QDs was characterized by Raman spectroscopy (Renishaw in Via Reflex) with 532 nm excitation source and 0.65 mW laser power. The absorption spectra and photoluminescence (PL) measurements of InP and ZnO QDs in ethanol and cyclohexane solvent were characterized by Cary 4000 of Agilent and FS920 of Edinburgh, respectively. PL measurements used to evaluate the charge transferring behaviors at the interface of Gr/QDs were characterized by a Jobin Yvon HR 640 monochromator with a 325 nm He–Cd laser as the excitation source. The photovoltaic performance of the QDs/Gr/GaAs solar cells was tested with a solar simulator under AM1.5G condition at illumination intensity of 100 mW cm\(^{-2}\). The illumination intensity was calibrated with a standard Si solar cell. The current density–voltage (J–V) data were recorded using Agilent B1500A system.

### 3. Results and discussion

InP and ZnO QDs are transferred to carbon grid for TEM characterizations to reveal the morphology and lattice structure of QDs. Fig. 2 shows TEM images of these two kinds of QDs in different magnifications and their electron diffraction pattern. Fig. 2(a) and (c) show the low-magnification TEM images of InP and ZnO QDs. From the high-magnification TEM images shown in Fig. 2(b) and (d), we can draw a conclusion that these two kinds of QDs possess a high crystal quality and average diameters of InP and ZnO QDs are about 5 nm and 15 nm, respectively. Moreover, the insets show electron diffraction pattern of

![Fig. 2](image-url)
InP and ZnO QDs, where the diffraction lines can be well labeled by the lattice planes of InP and ZnO. Trilayer Gr for Raman measurements is transferred to SiO$_2$/Si substrate by wet transferring process, which is then coated with InP and ZnO QDs step by step. The corresponding Raman spectra of Gr are shown in Fig. 3(a). For as-grown Gr, there are three characteristic peaks locating at 1350 cm$^{-1}$, 1591 cm$^{-1}$ and 2695 cm$^{-1}$, corresponding to D, G and 2D peaks, respectively. After spinning these two kinds of QDs on the surface of Gr, the G peak blue-shifts to 1596 cm$^{-1}$, which indicates that p-doping of Gr is enhanced by coating InP QDs and ZnO QDs subsequently. Fig. 3(b) shows the absorption spectra of ZnO and InP QDs in ethanol and cyclohexane solvent, respectively. For InP QDs, absorbance at short wavelength is very high, while it is very weak at long wavelength, and the absorption peak locates around 485 nm. For ZnO QDs, the absorbance is even weaker than InP QDs and the absorption peak locates around 374 nm of ultraviolet wavelength. Actually, these measurements are consistent with their inherent band gap ($E_g$) structure. To be specific, InP QDs with an even smaller $E_g$ than ZnO QDs can absorb much more energy of incident light. Moreover, these two different kinds of QDs can absorb photon with different energy and their photo-inducing effect can be accumulated. At the same time, these two kinds of QDs possess weak absorbance in visible wavelength, so GaAs substrate can effectively absorb other available incident light.

Fig. 4(a) shows the PL spectra of InP and ZnO QDs in ethanol and cyclohexane solvent with the excitation laser line of 405 and 325 nm, respectively. For InP QDs, there is a visible luminescence (VL) band with a maximum at about 515 nm which corresponds to the band-to-band recombination (2.4 eV). For ZnO QDs, PL spectrum mainly contains an ultraviolet luminescence band with a maximum at about 380 nm and a VL band with a maximum at about 510 nm. Indeed, the phenomenon of phosphorescence band with a maximum at about 380 nm and a VL band corresponds to the band-to-band recombination (2.4 eV). For InP QDs, there is a visible luminescence (VL) band with a maximum at about 515 nm which corresponds to the band-to-band recombination (2.4 eV). For ZnO QDs, the absorbance is even weaker than InP QDs and the absorption peak locates around 374 nm of ultraviolet wavelength. Actually, these measurements are consistent with their inherent band gap ($E_g$) structure. To be specific, InP QDs with an even smaller $E_g$ than ZnO QDs can absorb much more energy of incident light. Moreover, these two different kinds of QDs can absorb photon with different energy and their photo-inducing effect can be accumulated. At the same time, these two kinds of QDs possess weak absorbance in visible wavelength, so GaAs substrate can effectively absorb other available incident light.

The schematic structure of enhanced Gr/GaAs heterostructure solar cell with ZnO and InP QDs is shown in Fig. 5(a), which consists of Au gate electrode, n-type GaAs substrate, trilayer Gr, Ag contact, ZnO and InP QDs. InP and ZnO QDs solution are dropped onto the surface of Gr/GaAs solar cell and gently baked for 3 min. $J$–$V$ curves of the Gr/GaAs solar cell with and without QDs under AM1.5G illumination are shown in Fig. 5(b). Without any QDs, the best PCE of device is 8.57% and the corresponding parameters of solar cell containing open circuit voltage ($V_{oc}$), short circuit current density ($J_{sc}$), circuit and fill factor (FF) are 0.67 V, 17.80 mA cm$^{-2}$, and 71.80%, respectively. After coating the InP QDs on surface of Gr at the front top of solar cell, $J_{sc}$ is increased to 22.02 mA cm$^{-2}$, $V_{oc}$ is slightly increased to 0.68 V, but FF is slightly decreased to 69.42%, so the PCE is evidently increased to 10.39%. To our best knowledge, this decreasing trend of FF primarily results from corresponding enhancement of Gr’s surface resistance. Then some ZnO QDs are spun on the surface of Gr, $J_{sc}$ is further increased to 24.41 mA cm$^{-2}$, resulting in the final PCE of 11.50%. Therefore, the PCE enhancement resulting from the photo-induced doping is distinct. In Fig. 5(c), $J$–$V$ curves of the Gr/ GaAs solar cells with and without QDs in the dark perform similar rectifying characteristics, from which ideality factor can be obtained through single-diode fitting based on the following eqn (1):

$$J = J_0 \exp \left( \frac{qV}{NIF} \right) - 1$$

Fig. 3 (a) Raman spectra of trilayer Gr without and with QDs underlying on SiO$_2$/Si substrate. (b) Absorption spectra of InP and ZnO QDs in corresponding solvent.
Based on thermionic-emission theory, saturation current density $J_0$ can be described as eqn (2):

$$J_0 = AT^2 \exp \left( \frac{-q\phi}{K T} \right)$$  \hspace{1cm} (2)

where $K$ is the Boltzmann constant, $N_{IF}$ is the junction ideality factor, $q$ is the value of electron charge, $T$ is the absolute temperature ($T = 293$ K), $A$ is the effective Richardson constant of n-type GaAs (8.16 A kcm$^{-2}$ K$^{-2}$), and $\phi$ is the junction barrier height related to the differences between the work function of trilayer Gr and n-GaAs at zero bias voltage. The $N_{IF}$ values for the device without and with QDs are 2.8, 2.6 and 2.3, respectively, which are larger than ideal factor. This downward trend of $N_{IF}$ is probably attributed to shrunken values of parallel resistance. Physical picture of electronic band alignment of QDs/Gr/GaAs heterostructure is shown in Fig. 5(d). GaAs substrate is heavily
n-doped with an electron concentration around $1 \times 10^{18}$ cm$^{-3}$. Being heavily n-doped, the work function of GaAs substrate is close to its electron affinity (4.07 eV). The electron affinity of Gr (the $D$-value of vacuum level and Dirac point) is about 4.6 eV (ref. 34) and its work function is varied depending on the doping concentration. Therefore, a depletion region is formed in the interface of heterostructure by a build-in barrier under van der Waals force due to a clear difference of work function between Gr and GaAs. Without QDs, the light-induced electrons and holes originated in GaAs are collected by GaAs and Gr, respectively. Although the carriers excited by short wavelength photons can be effectively collected, the excess carriers generated by long wavelength can be inefficiently collected owing to several micrometers of diffusion length. In the case can a part of photon be drowned. With some appropriate QDs upper surface of Gr/GaAs solar cell, the photo-induced holes in both GaAs and QDs can inject into Gr in atomic scale, which raises the collection of holes by Gr and brings about performance enhancement of solar cells.

Eventually, stability and repeatability of DQs/Gr/GaAs solar cell are well investigated. Statistical analysis of PCE is operated by ten samples of QDs/Gr/GaAs solar cells. Specifically, the PCE distribution of each of the ten samples of Gr/GaAs and QDs/Gr/GaAs solar cells is illustrated in Fig. 6(a) where the result of obviously enhanced PCE of solar cells can easily be observed after introducing QDs, fully illustrating the practicability of photo-induced doping of Gr/GaAs solar cells. Furthermore, two samples of solar cells with QDs under sunlight illumination for 10 days are randomly used for investigation of stability. As shown in Fig. 6(b), PCE degradation is as low as 0.61% for these solar cells, indicating photo-induced doping Gr/GaAs solar cell with good stability can be sustained operation.

4. Conclusion

In conclusion, an ingenious approach to obtain the even higher PCE of Gr/GaAs by making full use of solar energy has been proposed. Two kinds of semiconductor QDs, InP and ZnO QDs, are applied to improve the performance of Gr/GaAs solar cell by photo-induced holes doping of Gr. To be specific, the PCE of Gr/GaAs can be increased from original 8.57% to 11.50% after spinning InP and ZnO QDs step by step. Therefore, under this cooperative photo-induced doping, the final PCE is improved by 34.2%. Good stability of QDs/Gr/GaAs solar cell is also fully confirmed. Further work may be necessary to explore the relation between the different combinations of various QDs that can absorb photon with different energy. Overall, this paper provides an easy and feasible way to develop promising Gr/semiconductor heterostructure devices for photovoltaic and optoelectronic applications.
