Screen printable MWCNT inks for printed electronics

Heera Menon, Remadevi Aiswarya and Kuzhichalil Peethambharan Surendran

Development of oxidation resistant conductive inks with low curing temperatures is a challenging problem in printed electronics. The present work introduces a newly formulated room temperature curable conducting ink using multiwalled carbon nanotubes (MWCNTs) for printable electronic application. The organic vehicle composition of the ink is meticulously controlled based on their rheological characteristics. The ink was screen printed on different flexible substrates like paper, Mylar®, photopaper, cellulose acetate sheets and silicone rubber. A morphological study of the printed pattern was also performed using SEM and AFM. The electrical characterization of the ink printed on flexible substrates was studied and a sheet resistance of 0.5–13 Ω sq⁻¹ for three strokes was reported.

1. Introduction

The conductive ink industry has been booming to ever greater heights over the past few years. There are mainly two kinds of materials used for conductive inks: noble metal based (silver and copper) and carbon based materials (graphite and CNT). Each of these has their own defined features and advantages. In general, printable metals are either exorbitantly expensive (e.g. Au, Ag or Pt) or are subject to fast oxidation (e.g. Cu) which limit their wide usage in printed electronics. A promising addition to this list is the carbon nanotube (CNT), which is a lightweight inorganic structure with unique physical and electrical properties relative to traditional conductive materials.

In order to integrate carbon nanotubes in device fabrication, there are several techniques being used. Two of the major approaches adopted to deposit nanotubes at the selected areas of substrates are “grow in place” and “solution based printing” methods. Being an additive process, printing of CNT is considered as the simplest and cost effective method for transferring CNTs onto the substrate. Printed CNT coatings/thin films can be developed into solar cells, digital circuits, sensors and antennas. Printing of functional inks can be performed by numerous printing techniques like inkjet printing, flexographic printing, screen printing, roll to roll printing etc. Among all these techniques, screen printing is the most cost effective technique used where the ink poured on the partially masked screen is squeegeed to move across, resulting in its uniform transfer through the stencil openings, onto the substrate placed beneath it. Here, the alignment between the fabric screen mask and the substrate is rather easy compared to gravure printing, since the screen mask is semitransparent, and both the mask and the substrate are planar.

Developing a stable and screen printable ink using CNT has been a long time challenge, primarily due to the ink’s prerequisites such as to possess a low viscosity at high shear rate and a fast viscosity recovery time. For achieving these requirements, the dispersion of the CNT and its flow characteristics through the screen mesh have to be strictly controlled. Besides, the stability of CNT suspension is difficult to achieve because of the nanotubes’ inherent tendency to aggregate due to high Van der Waals attractions resulting in the formation of bundles or ropes. In 2009, Biswas et al. reported that highly stable CNT dispersions are possible by judiciously employing sodium dodecyl sulphate (SDS) and polyvinyl pyrrolidone (PVP) in the vehicle. As known, PVP is a polymer containing amide groups which can be cross-linked into a three-dimensional molecular network, and can act as a dispersant and binder at the same time. Furthermore, PVP being highly soluble in polar solvents like ethanol, phase separation could be avoided during the ink formulation. On the other hand, the dispersant, SDS has been known as an efficient dispersant for CNT dispersions in recent literature whose dispersion mechanism of CNT has been widely studied.

In the present paper, we report the development and properties of a novel conductive MWCNT ink formulation that can be printed on different flexible substrates like Mylar®, cellulose acetate, photopaper and silicone rubber, with high degree of adhesion. The ink was formulated with proper rheological profile for higher throughput coatings using the flat-bed screen printing technique. The choice and proportion of organic contents were tricky enough so as to enable curing of the ink at room temperature. The microstructure, adhesion strength and...

2.2 Instrumentation
The structure and microstructure of MWCNT and its printed
patterns were analysed by scanning electron microscopy (JEOL-
transmission electron microscopy (FEI Tecnai G2 30S-TWIN operated at 300 kV, FEI Company, Hillsboro, USA) and atomic force microscopy (Bruker Nano Inc., USA). The colloidal stability of the CNT ink was measured using a rheometer (Brookfield, R/S Plus, MA, USA). The adhesion test for printed pattern was done as per the ASTM standard (D 3359-97). The electrical properties of the printed patterns were measured using source meter by four probe method (Keithley 2450).

2.3 Ink formulation and printing
An ink composition contains four elements: solvent, filler, dispersant and binder. Here an organic solvent based nanotube ink was formulated with ethanol as the solvent. For filler, commercially available multiwalled carbon nanotube (MWCNT, 99%, OD: <60 nm, length: 3–8 μm) was used as received without any further purification or treatment. To ensure proper disso-
lution of the mixture, the solubility of different dispersants and
binder was checked prior to development of the ink. Finally,
sodium dodecyl sulphate and polyvinyl pyrrolidone were chosen as the suitable dispersant and binder respectively for the ink formulation. The components of the ink such as SDS, PVP, ethanol and MWCNT have to be mixed thoroughly to form a stable homogenous suspension. Generally used dispersion methods like bath and probe sonication were precluded since these methods would result in excessive evaporation of the solvent. Decisively, a controlled magnetic stirring technique was opted for blending the organic vehicle. The carbon nano-
tube ink preparation procedure begins with the addition of SDS
into 5 ml ethanol. The dispersant was added prior to the filler in
order to ensure proper suspension of the MWCNT and the
dispersant loading was optimized as 7.5 wt% of filler loading. The
MWCNT was added in to this mixture after 1 h of stirring which
was followed by the addition of PVP after 2 h. The PVP
loading was varied from 15 wt% to 50 wt% of CNT. The
complete mixture was thoroughly stirred for the next 24 h.

The MWCNT concentration in the ready-to-print ink was
found to be about 9 wt% with respect to the total solvent
content. The optimal concentration of the binder is required for
proper adhesion of the ink to the substrate. Further, it can
enhance the ink viscosity, debundle MWCNTs, stabilize the inks
for a long time, and improve the printed device patterns. On the
other hand, there should not be too much PVP in the inks which
may result in very high viscosity and deteriorate the electrical
conductivity.

The ink with optimal flow characteristics was screen printed on
different flexible substrates like paper, Mylar®, photopaper,
cellulose acetate sheet and silicone rubber using a semi-
automatic screen printer (XPRT2, Ekra, Asys group, Germany).
For printing, we used silk screens with mesh size 325 which is
tightly bound over a metallic frame of dimension 220 × 220 mm.

3. Results and discussion
As mentioned before, MWCNTs consists of multiple rolled
concentric graphene tubes which can be metallic or semi-
conducting. Fig. 1(a) and (b) represent TEM analysis of CNTs. It
is observed that the CNTs we tested are multiwalled with
diameter of the nanotubes ranging from 65–80 nm with lengths
in micrometer range. The walls of the CNTs are distorted which
may be attributed to the synthesis conditions. Fig. 1(a) re-
presents a bamboo like CNT (BCNT). It is so called because nano-
tubes structure resembles the structure of bamboo. Here, the
graphite layers are misaligned with the primary MWNts axis. It
is reported that bamboo defects consist of several transverse,
internal walls segmenting the interior of a MWNt into inde-
pendent pods or isolated volumes. Bamboo defects are often
quasi-periodic and by nucleating new shells they maintain
roughly constant outer diameters. As stated in the literature,
the diameter of the nanotube increases, metallic nature of the
tube also predominates.

Rheological optimization of MWCNT ink is an important
reliability criterion. Viscosity is a crucial parameter in opti-
mizing the ink. Fig. 2 shows the viscosity studies of formulated
MWCNT ink. For screen printing purpose the viscosity must be
in the range of 1–10 Pa s which means the ink must neither be
too loose nor too viscous. This is because loose ink will result in
overflowing solvent, thus making it unprintable. On the other
hand, if the ink is too viscous, then it would be difficult to
spread it with the squeegee. As the amount of filler increases the
viscosity tends to increase and vice versa. In other words, as
more and more CNT is added, the ink becomes more concen-
trated and hence improves the viscosity. When the dispersant
increases, it tends to disperse the CNT more uniformly, weak-
ening the impact of agglomeration and thus decreasing the
viscosity.

Fig. 2(a) represents the change in viscosity with increase in
binder. In this work, the binder used was PVP. Here, this

![Fig. 1](a) and (b) shows TEM of multiwalled carbon nanotube.)
flourine free polymer can act both as dispersant and binder, which can facilitate better dispersion of CNT bundles into a 3D continuous network. When the PVP weight loading is increased from 15 to 45 wt%, there is decrease in the viscosity. This is because it is the dispersion effect of PVP that dominates more in this case. But as the weight loading is increased to 50 wt%, there is an increase in viscosity implying that it starts behaving as a binder. The optimized concentration of PVP was observed to be 50 wt% with respect to filler loading. In Fig. 2(b), the final viscosity of the optimized ink is obtained as 2.09 Pa s. This ink possesses ideal flow characteristics suitable for screen printing.

The SEM analysis (Fig. 3) of the printed pattern was performed to understand the surface morphology and thickness of the printed pattern. Fig. 3(a) and (b) show uniformly distributed CNT networks as seen from the surface of the printed area. Here, the CNTs form connected networks which enhance the

conducting nature of the printed pattern. It is signified from the images that the surface coverage is not due to the CNTs alone but a cluster of as grown CNTs and the binding material. Fig. 3(c) depicts the cross sectional view of the printed area which helps us to understand the thickness of the printed pattern. It was observed that the apparent thickness falls in the range 20–25 μm.

The RMS surface roughness quantifies the deviations from the mean surface, which helps to understand how the pattern appears to be, after the vaporization of the solvents. Atomic force microscopy was adopted to study the surface roughness of the printed pattern surface which is presented in Fig. 4. Different areas of the sample have been analysed and a couple of typical tapping mode micrographs are given in Fig. 4(a) and (b). The RMS surface roughness obtained was 64.4 nm, which is comparable to the roughness value reported in the literature. A more uniform surface would result in uniform sheet resistance, as the resistance is entirely depended on the connectivity of CNTs.

The adhesion test was done as per the ASTM standard (D 3359-97) and a few optical micrographs recorded after the test is shown in Fig. 5. Adhesion is one of the key properties that characterize a conducting ink. The sheet resistance of the printed pattern was measured using a four probe measurement set up and the I–V plot is as shown in Fig. 7(a). The sheet

resistance was found to vary from sample to sample, depending on the connectivity of the CNT network. A well-connected CNT network of three strokes attained a sheet resistance of 0.5 Ω sq⁻¹. At the same time, a sheet resistance of 13 Ω sq⁻¹ was obtained in another three stroke printed sample which is believed to have an inferior network connection. The electrical conductivity of the printed pattern depends also on the adhesion of the CNT network to the substrate. A least adhered pattern would emanate in a highly resistive network. It was concluded that it would require higher weight loading of binder in order to print the ink on silicone rubber substrate for proper adhesion when compared to the other rough substrates like cellulose acetate, Mylar® and photopaper. The sheet resistance of the present ink was comparable with those reported in recent literature. Table 1 shows the comparison based on sheet resistance and printing method for other nanocarbon inks and silver based inks.

The newly developed ink bypasses the high temperature curing, which is a pre-requisite for majority of the MWCNT based inks. Since the present formulation enables efficient 3D networked connected structure for MWCNT, it could offer improved electrical conductivity. This in turn, helps us to design facile development of conductive circuits employing MWCNT. As shown in Fig. 7(b), typical circuits like microwave patch antennas could be designed and screen printed using this facile methodology.

4. Conclusions
Development of novel conducting inks is a new direction in the field of printed electronics. Most of the commercial conductive inks available in the market are made of noble metals and requires stringent operating conditions to protect them from imminent oxidation. Furthermore, a majority of the inks require an annealing at temperature around 140 °C, in order to dispel away the high volatile vehicle holding the conductive filler particles, which is disadvantageous. Due to these reasons, the development of a room temperature curable ink, which does not suffer from oxidation problem, is a challenging task in flexible electronics. In the present work, a room temperature curable conducting MWCNT ink was formulated using suitable solvents, dispersants and binders. Here flatbed screen printing is the technique employed to print CNT ink on various flexible substrates like paper, Mylar®, cellulose acetate sheet and photopaper. Characterization of the CNT were done using TEM which indicated the presence of as grown MWCNT with distorted walls and many of them assume the structure of bamboo-like CNTs (BCNTs). The CNT ink printed on flexible substrates exhibited outstanding adhesion characteristics as per ASTM standard D3359-97 and sheet resistance in the range of 0.5–13 Ω sq⁻¹ with minimum surface roughness (<65 nm).
