# High-performance transparent ultraviolet photodetectors based on inorganic perovskite CsPbCl<sub>3</sub> nanocrystals

Jingru Zhang,<sup>a</sup> Qian Wang,<sup>\*a</sup> Xisheng Zhang,<sup>a</sup> Jiexuan Jiang,<sup>a</sup> Zhenfei Gao,<sup>c</sup> Zhiwen Jin<sup>id</sup><sup>\*a</sup> and Shengzhong (Frank) Liu<sup>id</sup><sup>\*ab</sup>

Inorganic lead halide perovskite nanocrystals (CsPbCl<sub>3</sub> NCs) with excellent ultraviolet (UV) light absorption, high carrier mobility, long carrier diffusion lengths, and long-term stability are good candidates as smart materials for transparent optoelectronic devices. In this study, transparent UV photodetectors (PDs) based on CsPbCl<sub>3</sub> NCs were fabricated for the first time. The optimized device exhibited visible light transmittance approximately 90%, strong absorption of UV light in the wavelength from 300 nm to 410 nm, good photoresponsivity (1.89 A W<sup>-1</sup>), and a high on/off ratio (up to 10<sup>3</sup>). Meanwhile, the rise and decay response times of the device were less than 41 ms and 43 ms, respectively. Furthermore, we performed detailed analysis of the effects by employing CsPbCl<sub>3</sub> NCs in assembled films and final devices using various characterization methods. The simple fabrication and remarkable UV photodetection capabilities of CsPbCl<sub>3</sub> NCs make them promising semiconducting candidates in optoelectronic applications.

## Introduction

It is highly desirable for optoelectronic devices to be visually transparent for applications in both civilian and military fields, such as fire and missile plume detection and optical communications.<sup>1–5</sup> In particular, UV detection with high discrimination against visible and infrared light is ideal for detection in the background of infrared and visible radiation. For such emerging applications, visible-transparent ultraviolet (UV) thin film photodetectors (PDs), as important electronic devices and essential building blocks for electronic systems, have attracted substantial research attention in recent years.<sup>6,7</sup> For ideal “visible-blind” UV PDs, it is desirable for the active component to have high UV light responsiveness, significant visible light rejection, and a linear photocurrent-optical power correlation. Structural simplicity, low-cost fabrication, and low-temperature operation are also crucial for use in commercial applications.<sup>8,9</sup>

ZnO is an important material for transparent UV PDs due to its ease of fabrication, environment friendliness, and ideal bandgap of 3.2 eV.<sup>10,11</sup> Despite progress, the steady-state response

of ZnO usually lasts between 30 s and 200 s, because of adsorption and desorption of O<sub>2</sub> trapping states.<sup>12,13</sup> Synthesizing novel ZnO-based nanocomposites by modifying the surface of ZnO is a promising solution. In the past decades, there have been numerous reports on the surface capping of ZnO using inorganic materials, organic materials, carbon materials, and Au nanoparticles. However, the effect is still not ideal.<sup>14–17</sup> In parallel, oxide semiconductors are usually n-type, making it difficult to realize transparent systems with complementary circuits.<sup>18</sup>

To develop the next generation of UV-transparent PDs, new semiconductor materials with easy fabrication, strong light absorption, high charge carrier mobility, stability in air, few defects, and bipolarity are needed. In particular, perovskites possess the merits of high charge carrier mobility and strong light absorption 10 times greater than those of organic dyes, small exciton binding energies, and long carrier diffusion lengths of up to 175 μm, making them promising candidates for use in such PD applications.<sup>19–25</sup> More recently, inorganic perovskites CsPbX<sub>3</sub> (X = Cl, Br, I) have attracted research efforts as future optoelectronic materials since they are more stable in air than organic–inorganic perovskite materials.<sup>26–30</sup>

Inorganic perovskite CsPbCl<sub>3</sub> is a wide-bandgap semiconductor, which is transparent to visible radiation but sensitive to UV radiation.<sup>31</sup> Such absorption, mainly limited to wavelengths shorter than 400 nm, makes it attractive for visible-blind UV detection. In recent years, the optical bandgap of CsPbCl<sub>3</sub> has been adjusted by reducing the crystallite size to the nanometer scale to form nanocrystals (NCs).<sup>32,33</sup> The optical bandgap increases as the size decreases, making CsPbCl<sub>3</sub> NCs

capable of meeting the different requirements of various fields applications. However, to the best of our knowledge, no efficient UV detection devices have yet been developed based on CsPbCl<sub>3</sub> NCs.

In this study, we analyzed in detail the effects of employing CsPbCl<sub>3</sub> NCs in assembled films and final devices. Furthermore, we designed the first transparent UV PD based on inorganic CsPbCl<sub>3</sub> NCs. The fabricated device exhibited high UV sensitivity ( $1.89 \text{ A W}^{-1}$ ), a high on-off current ratio ( $10^3$ ), short rise and decay times (41 ms and 43 ms, respectively), and long-term photostability, which suggesting that CsPbCl<sub>3</sub> NCs have great potential for use in high-performance transparent UV PDs.

## Results and discussion

Solution-processing techniques have been used to fabricate the CsPbCl<sub>3</sub> NCs. Spin-coating was used to fabricate CsPbCl<sub>3</sub> NCs

films for high-performance PD devices. First, we compared CsPbCl<sub>3</sub> NCs prepared at a low temperature (90 °C) in various reaction times (5 s, 10 s, and 20 s). We found evidence to support the previous reports that CsPbCl<sub>3</sub> NC formation occurs through seed-mediated nucleation and that further growth occurs through self-assembly and oriented attachment.<sup>34</sup> The typical high-resolution transmission electron microscope (HRTEM) images presented in Fig. 1a–c reveal the fine crystal-line structures of the CsPbCl<sub>3</sub> NCs, indicating assemblies of quantum dot (QD), platelet, and cubic CsPbCl<sub>3</sub> NCs, respectively, with dimensions of about 5–20 nm.

It is found that monodispersed spherical CsPbCl<sub>3</sub> quantum dots (QDs) are well-separated and uniform in size with diameter  $\sim 5$  nm. This is confirmed by transmission electron microscope (TEM), as shown in Fig. 1a. The high-resolution TEM (HR-TEM) imaging reveals that the QDs are highly crystalline in structure. As shown in Fig. 1a, the lattice fringes of the CsPbCl<sub>3</sub> QDs have a spacing of *ca.* 0.31 nm, well in agreement with the interplane spacing of the cubic-phase CsPbBr<sub>3</sub> for the (111) crystal planes.<sup>35</sup> As the reaction time rises from 5 s to 10 s, colloidal CsPbCl<sub>3</sub> platelet was formed with obvious morphology shown in Fig. 1b. Careful measurements indicate that the CsPbCl<sub>3</sub> nanocubes are *ca.* 10 nm in length. The HR-TEM image reveals that the lattice fringe of a represent cubic is 0.54 nm, in consistent with the (001) plane of cubic crystal structure CsPbCl<sub>3</sub>.<sup>35</sup> By further enhanced the reaction times (20 s), the CsPbCl<sub>3</sub> cubics were synthesized. As presented in Fig. 1c. The HR-TEM image (Fig. 2f) highlights the CsPbCl<sub>3</sub> cubics with a well-defined crystalline structure with a cubic lattice parameter of 0.54 nm, along with the crystalline direction of (001).<sup>35</sup>

It is well known that the NC quality (purity and solubility) is important to fabricate large-area, crack-free, low-roughness perovskite thin films. Here, we demonstrated a highly efficient purification process involving using a hexane/methyl acetate (MeOAc) mixed solvent to control the surface ligand density on

Fig. 1 (a)–(c) Typical HRTEM images of CsPbCl<sub>3</sub> NCs obtained using different reaction conditions. TEM images of cubic CsPbCl<sub>3</sub> NCs after washing (d) two, (e) four, and (f) six times.

the CsPbCl<sub>3</sub> NCs to realize the high purity and solubility. The transmission electron microscopy (TEM) images that obtained after washing the cubic CsPbCl<sub>3</sub> NCs two, four, and six times are exhibited in Fig. 1d–f, respectively. The grain corners gradually become blurred as the number of washings increases. Thus, excessive purification resulted in obvious aggregation and precipitation due to the serious loss of surface ligands. Based on these results, it was decided to wash the CsPbCl<sub>3</sub> NCs only two times for purification.<sup>36</sup>

In order to investigate the microstructure and morphology of the CsPbCl<sub>3</sub> thin films, atomic force microscope (AFM) measurements were performed. Fig. 2a–c present AFM images of the individual films based on QD, platelet, and cubic CsPbCl<sub>3</sub> NCs, respectively, and clearly reveal the small CsPbCl<sub>3</sub> grains. Fig. 2d–f display AFM images of the films fabricated with CsPbCl<sub>3</sub> cubic purified at different times (two, four, and six times, respectively). The film used the CsPbCl<sub>3</sub> cubic that was washed twice is clearly smooth and uniform. However, the film became cracked after the cubic washing four times. Furthermore, washing six times caused a large number of holes to form in the cubic CsPbCl<sub>3</sub> film, which would extend the carrier transport length. These results also indicate that the film quality is the best after washing twice.<sup>37</sup>

The cubic CsPbCl<sub>3</sub> NC-based PD is illustrated schematically in Fig. 3a. The device contains a typical ITO/CsPbCl<sub>3</sub> NCs/quartz stack: the CsPbCl<sub>3</sub> NC film was fabricated by spin-coating approach with 100 nm thickness; afterwards, a pair of interdigitated ITO electrodes (100 nm thick) was thermally evaporated onto the films through a shadow mask, resulting in a channel width/length ratio of  $200 \mu\text{m}/5 \mu\text{m}$ . Fig. 3b shows a typical X-ray diffraction (XRD) pattern of cubic CsPbCl<sub>3</sub> NCs.

Apparently, the CsPbCl<sub>3</sub> crystallizes into a cubic structure ( $Pm3m$  space group) with no observable impurity phases.<sup>38</sup> The absorption and photoluminescence (PL) spectra were measured and are presented in Fig. 3c. The CsPbCl<sub>3</sub> NCs exhibit strong absorption from 300 nm to 410 nm and a narrow band-edge emission peak at 402 nm, which is consistent with the literature.<sup>39,40</sup> The absorption implies that PDs based on CsPbCl<sub>3</sub> NCs will intrinsically be visible-blind.

The PD fabricated using cubic CsPbCl<sub>3</sub> NCs shows approximately 90% optical transmittance in the visible light region. For comparison, the transmittance spectra of the bare substrate and transparent electrode are also collected in Fig. 3d. The worse transmittances of the transparent electrode and CsPbCl<sub>3</sub> PD in the UV region, especially for the CsPbCl<sub>3</sub> PD, are attributable to strong absorption in the UV region. The photograph inserted in Fig. 3d confirms that the PD has high transparency. Note that the green plants behind the transparent device can easily be seen. Fig. 3e provides the dark and light  $I$ – $V$  curves of the CsPbCl<sub>3</sub> PD, where the light curve was obtained under 365 nm illumination ( $10 \text{ mW cm}^{-2}$ ). The device exhibits a high signal-to-noise ratio of about  $10^3$ , implying that the PD is highly sensitive, which may be attributable to the high light-absorption efficiency of the CsPbCl<sub>3</sub> NCs.<sup>41</sup>

The CsPbCl<sub>3</sub> PD also exhibits high spectral selectivity (photocurrent and responsivity ( $R$ )), which can clearly be seen in Fig. 3f. The  $R$  is given by the following equation:<sup>42</sup>

$$R = \frac{I_{\text{light}} - I_{\text{dark}}}{P_{\text{ill}}}, \quad (1)$$

where  $I_{\text{light}}$  is the current density under illumination,  $I_{\text{dark}}$  is the dark current density, and  $P_{\text{ill}}$  is the power density of the incident illumination. It is evident that the photocurrent increases above

Fig. 4 (a) On-off switching properties measured under 365 nm light illumination ( $10 \text{ mW cm}^{-2}$ ) at a bias of 5 V. (b) Time-resolved photocurrent of the fabricated PD. (c) On-off cycling test results measured under 365 nm light illumination ( $10 \text{ mW cm}^{-2}$ ) at a bias of 5 V. (d) Fit curve for photocurrent versus incident optical power. (e) Absorption spectra of CsPbCl<sub>3</sub> in QD, platelet, and cubic form. (f) On-off switching properties of the PDs based on CsPbCl<sub>3</sub> in QD, platelet, and cubic form.

the bandgap energy of the CsPbCl<sub>3</sub> NCs (3.1 eV at a wavelength of 400 nm), confirming the intrinsic visible-blindness of the CsPbCl<sub>3</sub> PD. When the wavelength is 450 nm, the photocurrent is very low since the incident light energy is less than the bandgap of the CsPbCl<sub>3</sub> NCs. However, when the wavelength is shorter than 365 nm, the photocurrent decreases gradually with decreasing wavelength, which is mainly due to the different external quantum efficiencies of the materials, as previously reported.<sup>43</sup> The PD exhibits the strongest response to 365 nm light. Therefore, 365 nm light was employed to assess the performance of the CsPbCl<sub>3</sub> PD.

The time-dependent photoresponse of the PD measured by periodically turning it on and off in 5 s intervals is presented in Fig. 4a. The photocurrent rapidly increases to a stable peak value ( $1.89 \times 10^{-7} \text{ A}$ ) upon the application of 365 nm illumination and

then quickly decreases to its initial value ( $1.71 \times 10^{-10} \text{ A}$ ) upon the light being turned off, revealing that the CsPbCl<sub>3</sub> PD has highly stable and reproducible characteristics. It should be noted that the rise time and decay time of the PDs are defined as the time taken for the initial current to increase or decrease to 90% of the peak value, respectively.<sup>44</sup> The rise and decay times of the present device are 41 ms and 43 ms (Fig. 4b), respectively, indicating that the CsPbCl<sub>3</sub> PD has ultra-fast responses compared to those of the traditional transparent ZnO-based UV PDs, whose typical response speeds have been reported to be tens or hundreds of seconds (seen in Table 1).<sup>45–52</sup> The on/off cycle testing results are depicted in Fig. 4c. After 1000 repeated on/off cycles, the on current ( $1.83 \times 10^{-7} \text{ A}$ ) and off current ( $1.81 \times 10^{-10} \text{ A}$ ) do not suffer any appreciable deterioration, and the

**Table 1** Comparison of the characteristic parameters of photodetectors

Films	Rise time (s)	Decay time (s)	$R$ ( $\text{A W}^{-1}$ )	Reference

device maintains a high on/off ratio above  $10^3$ . These parameters are beneficial for practical applications.

Fig. 4d shows the photocurrent and photoresponsivity ( $R$ ) as a function of the light intensity. The photocurrent increases as the illumination intensity increases, which is as expected since the number of photogenerated carriers is proportional to the absorbed photon flux. The fit line reveals that the photocurrent is proportional to the light intensity. In this study, the highest value of  $R$  was found to be  $1.89 \text{ A W}^{-1}$  upon device optimization. Compared with other traditional transparent materials based UV PDs (seen in Table 1),<sup>45–52</sup> the remarkably photo-response performance by the CsPbCl<sub>3</sub> PDs is attributed to its larger crystal size, which are favorable for carrier mobility, leading to enhanced photoresponse.

The absorbing properties of the QD, platelet, and cubic CsPbCl<sub>3</sub> PDs as determined using UV-vis spectroscopy are presented in Fig. 4e. To the best of our knowledge, the optical bandgap increases as the NC size decreases.<sup>53,54</sup> Therefore, the optical bandgap can be tuned by adjusting the reaction conditions in the CsPbCl<sub>3</sub> NC synthesis process at  $90^\circ\text{C}$  using various reaction temperatures.<sup>55</sup> The optical absorption spectra of all of the PDs (Fig. 4e) show intense absorption in the UV region. Evidently, the optical bandgap of the CsPbCl<sub>3</sub> NCs is redshifted as the crystal size increases (from QD, to platelet, to cubic), which is consistent with other reports.<sup>56</sup>

The  $I$ - $t$  curves of the QD, platelet, and cubic CsPbCl<sub>3</sub> PDs are presented in Fig. 4f for comparison. All of the PDs exhibit high current responses to the UV light and excellent on-off switching performances. The distinction among the three types of CsPbCl<sub>3</sub> NCs is that the peak current intensity increases as the crystal size increases, since the carrier mobility increases simultaneously. Large particles will reduce the number of the interface defects, resulting in higher carrier mobility and photocurrent.<sup>57</sup>

## Conclusions

In conclusion, we performed detailed analysis of the effects of employing CsPbCl<sub>3</sub> NCs in assembled films and final devices using various characterization methods and finally successfully fabricated a high-performance transparent UV PD from solution-processed inorganic perovskite CsPbCl<sub>3</sub> NCs. The strong UV

absorption and high visible light transmittance indicate that the CsPbCl<sub>3</sub>-based UV PD is intrinsically visible-blind. As a result, the device exhibits good responsivity ( $1.89 \text{ A W}^{-1}$ ), a high on/off ratio ( $10^3$ ), and stable properties after 1000 repeated on/off cycles. Furthermore, the rise and decay times of the present device are 41 ms and 43 ms, respectively, indicating that CsPbCl<sub>3</sub> PDs possess ultra-fast responses compared with the traditional transparent UV PDs. Finally, our investigation of the influence of using different sizes of CsPbCl<sub>3</sub> crystals in UV PDs revealed that cubic CsPbCl<sub>3</sub> crystals yield the highest photocurrent intensity due to the increase in carrier mobility with increasing size. All of these results demonstrate that inorganic perovskite CsPbCl<sub>3</sub> NCs are among the most effective semiconductors for use in high-performance transparent UV PDs.

## Experimental section

### Materials preparation

Synthesis of CsPbCl<sub>3</sub> nanocrystals: Cs<sub>2</sub>CO<sub>3</sub> (0.415 g), 1-octadecene (ODE, 18 ml), and oleic acid (OA, 1.76 ml) were added to a round-bottom flask and stirred under a vacuum for 30 min at  $120^\circ\text{C}$  as Cs-oleate. PbCl<sub>2</sub> (0.25 g), ODE (10 ml), OA (1.6 ml), and Oleylamine (OAm, 1.6 ml) were stirred in another round-bottom flask and degassed under a vacuum at  $90^\circ\text{C}$  for 1 h before filling the flask with N<sub>2</sub>. Then, the Cs-oleate (0.8 ml) was swiftly injected into the reaction mixture at  $90^\circ\text{C}$ . The reaction was quenched by immediate immersion of the flask into an ice bath for different times. The synthesized CsPbCl<sub>3</sub> NCs (QD, platelet, and cubic) were precipitated by adding 200 ml MeOAc. This process was repeated twice, and the CsPbCl<sub>3</sub> NCs were finally dispersed in hexane with a concentration of  $50 \text{ mg ml}^{-1}$ .

### Device fabrication

The PD fabrication process was as follows: the CsPbCl<sub>3</sub> layer was fabricated by spin-coating a solution of the relevant CsPbCl<sub>3</sub> NCs (QD, platelet, or cubic) onto a cleaned quartz substrate at 2500 rpm for 15 s. To form the high-mobility and low-trap density CsPbCl<sub>3</sub> layer, the prepared film was quickly dipped into a neat MeOAc solution and then a saturated Pb(OAc)<sub>2</sub> MeOAc solution. This process was repeated four times, producing CsPbCl<sub>3</sub> films with thicknesses of about 100 nm. All of the spin-coating steps were performed in ambient air. Finally, a pair of interdigitated ITO electrodes (100 nm thick) was thermally evaporated onto the films through a shadow mask, resulting in a channel width/length ratio of  $200 \mu\text{m}/5 \mu\text{m}$ .

### Characterization

All of the electrical characteristics were recorded with an Agilent B2902A in ambient air. The monochromatic light was from a Newport Oriel 200™. Prior to the utilization of the light, the spectral and the light intensity were calibrated using a mono-silicon detector. The TEM images were taken by a JEM-2100 JEOL TEM. The surface morphology was characterized by using an AFM (Dimension ICON). The thickness of the films was determined using a Profilometer. UV-vis spectra were recorded using a JASCO V-570 spectrophotometer. The samples

were excited by a laser (Omni- $\lambda$ 300), with a wavelength of 365 nm. The mechanical optical choppers are used to control the laser on/off. The phase compositions of the samples were characterized by a DX-2700 XRD using Cu K $\alpha$  radiation ( $\lambda$  = 0.15418 nm) in a  $2\theta$  range of 10–50°.
