Effect of xylose on the structural and physicochemical properties of peanut isolated protein based films

Li Liu,  ^{†ab} Wei-Jing Lin, ^{†a} Hong-Zhi Liu, ^a Ai-Min Shi, ^a Hui Hu, ^a Mehmet Nail Nasir, ^b Magali Deleu ^{*b} and Qiang Wang ^{*a}

Films based on xylose and peanut protein isolate (PPI) were prepared by solution casting. The effects of xylose content (1%, 2%, 5%, 10%, 20% PPI, w/w) on the structure and mechanical properties of PPI–xylose (PPI–X) film were systematically investigated. The xylose-modified PPI was firstly prepared by crosslinking and modifying of peanut isolated protein with xylose. The degree of glycosylation and surface hydrophobicity significantly increased from 5.6% to 10.9% and from 130.6 to 370.0, respectively, with the increase of the xylose content. Maillard reactions occurring between PPI and xylose were confirmed by Fourier transform infrared spectroscopy. Then the xylose-modified PPI was developed into films. PPI–X films showed markedly increased tensile strength (increased by 77%) and elongation (increased by 67%) and decreased solubility (from 96.6% to 43.4%) compared to PPI films, suggesting that the incorporation of xylose could markedly enhance the mechanical properties and the water resistance of films. This property improvement was correlated to the increased protein surface hydrophobicity and sulfhydryl group content with the addition of xylose. No significant differences were detected among L^* , a^* , b^* colour values of all films ($P > 0.05$). The scanning electron microscope images of the PPI–X film showed that the addition of xylose up to 10% produced a more homogeneous and denser structure. Finally, the improvement mechanism of the PPI–X film was proposed.

1. Introduction

Biodegradable films have gained increasing research interest due to their potential use in food packaging. They are obtained from renewable and natural biopolymers such as proteins, polysaccharides and their combinations. Among them, protein-based materials such as soybean, wheat gluten, and peanut protein films are the most attractive candidates to replace non-biodegradable plastics because they are environmentally friendly, and have similar physical and mechanical properties compared to synthetic films.^{1–4}

Peanut meal is a byproduct generated during oil extraction and is mainly used as animal feed and fertilizer in China.³⁶ Peanut protein isolate (PPI), extracted from peanut meal, has a low cost, presents good biodegradability and ability to

polymerize, and could then be a good source to develop films for various applications.⁵

However, protein-based films have relatively low tensile strength, low elongation and water resistance compared to synthetic films, due to the hydrophilicity of plant proteins.⁵ The crosslinking or blending with polymers is one approach used to make the protein films suitable for practical use. Most protein-based films use glycerol as a plasticizer to improve the elongation of the film. Modification of peanut proteins by glycosylation or cross-linking with saccharides is a potential way to improve the mechanical strength and the barrier properties of the films by reinforcing the intermolecular bonds.^{6–8}

In literature, several recent papers deal with the improvement of the mechanical and barrier properties of protein-based films by glycosylation reactions.^{4,9,10} Glycosylation with gum arabic¹¹ or glucomannan⁹ increases the tensile strength, decreases the water vapor permeability of protein films, but decreases the elongation ability. Generally, plasticizers having a smaller molecular weight show an easier incorporation into the protein matrix than plasticizers with a larger molecular weight.^{12,13} They also exhibit a more efficient plasticizing effect and lead to a stronger and tighter protein networking with stronger intermolecular covalent bonds. Lin *et al.*^{4,7} reported that crosslinking with xylose increases the strength and elongation of peanut protein films and also decreases quite

[†] Li Liu and Wei-Jing Lin contributed equally to this article.

remarkably their solubility in water. Therefore, xylose could be a good choice for the formation of protein-polysaccharides films. A previous study was focused on the optimization of pH, temperature and time of reaction to obtain the xylose glycosylated protein (PPI-X) solutions.⁴ The effect of PPI-X dissolution temperature and glycerol concentration on mechanical properties and water solubility of glycosylated films were also investigated.⁷ However, only little information exists on the molecular structure and physicochemical properties of peanut protein films cross-linked with different xylose content.

In this context, one goal of this work was to provide an array of data to support comparative characterization of PPI film, at various levels of addition of xylose (1%, 2%, 5%, 10%, 20%, w/w). In this research, peanut protein isolate (PPI) was glycosylated with xylose, and the glycosylated PPI solution was converted into powder. The effect of xylose on the structure of xylose-modified PPI was analyzed in detail. In addition, the glycosylated PPI was used to form films. The effects of glycosylation on the tensile strength and elongation, solubility in water, color, sulfhydryl groups content and microstructure of PPI-X films were evaluated. Finally, the mechanism of PPI-X film formation was also proposed.

2. Materials and methods

2.1. Materials and chemicals

Peanut meal with a protein content of 47.81% was purchased from Gaotang Lanshan Co., Ltd. (Shandong Province, China). Xylose, NaOH and NaBr (Sinopharm Chemical Reagent Co., Ltd., Beijing, China) used in the experiments were analytical grade and used without further purification.

2.2 Preparation of peanut protein isolated (PPI)

Peanut protein isolate (PPI) was extracted from the peanut meal according to previous study with slight modifications.⁴ Briefly, peanut meal was dissolved in (1 : 10, w/v) deionized water, the pH of dispersions was adjusted to 9.0. After stirring with 150 rpm for 2 h at 25 °C, the supernatant was obtained by centrifuging at 3500g for 10 min. The pH of the supernatant was adjusted to pH 4.5. After centrifuging at 3500g for 10 min, the precipitate (peanut protein isolated) was recovered and freeze dried. The protein content was $90.93 \pm 1.36\%$.

2.3 Preparation of xylose-modified PPI powder

PPI was modified with xylose by glycosylation, at five different ratios of xylose: 0.01 g, 0.02 g, 0.05 g, 0.10 g, 0.20 g g⁻¹ PPI. The pH was adjusted to 9.0 using 1 mol L⁻¹ NaOH and the solutions were heated at 90 °C for 90 min. The mixtures were then spray-dried to obtain the PPI-X powder.

2.4 Film preparation

The film-forming solutions were prepared by dispersing PPI, or xylose-modified PPI in distilled water (5%, w/w). Glycerol was added at 25% of the total components. After degassing by filtering through nylon filters, 15 mL of the film forming solutions were poured onto nonstick plates (15 cm diameter). Films

were dried at 60 °C for 1 h and peeled entirely after cooling. The peeled films were conditioned at 58% relative humidity (RH) for at least 48 h prior to analysis.

2.5. Structural characterization of the xylose-modified PPI powder

2.5.1. Determination of the degree of glycosylation. The degree of glycosylation (DG) of PPI-X powder were determined by applying the method using OPA (*o*-phthalaldehyde) as described by Zhang *et al.*¹⁴

2.5.2. Surface hydrophobicity. The surface hydrophobicity (H_0) of PPI-X was determined according to the method of He *et al.*¹⁵ using 1-anilinonaphthalene-8-sulfonic acid (ANS) as the fluorescence probe. Protein solution (1 mg mL⁻¹) was prepared in PBS (10 mM, pH 7.0). After incubation at 20 °C for 2 h, the mixture was centrifuged at 10 000g for 20 min. Protein concentration of the supernatant was determined with Folin phenol method. Fluorescence intensity was measured at 490 nm after excitation at 390 nm. The initial slope of fluorescence intensity *versus* protein concentration plot was used as an index of H_0 .

2.5.3. Fourier transform infrared spectroscopy (FTIR). FTIR of xylose, PPI and PPI-X were carried out on a FTIR spectrophotometer (Bruker, Madison, USA). The sample was ground with spectroscopic grade potassium bromide (KBr) powder and then pressed into a 1 mm pellet for FTIR measurement in the frequency range of 4000–400 cm⁻¹.

2.6. Characterization of the mechanical, structural and physical properties of the films

2.6.1. Mechanical properties. Tensile strength (TS) and elongation at break (E) of all films were determined using a TA-TX2i texture analyzer (Stable Micro System Ltd., Godalming, UK) according to ASTM standard method D882-01.

2.6.2. Physical properties

2.6.2.1. Solubility in water. The total soluble matter (TSM) of the films was calculated by employing the method described by Lin *et al.*⁷ The initial dry matter of the preconditioned film pieces (2 × 2 cm) was determined by drying in an air-circulating oven at 105 °C for 24 h (W_i). The insoluble matter was separated carefully and dried at 105 °C for 24 h for determination of the final dry weight (W_f). All tests were carried out in triplicate, and the total soluble matter (%) in the film was calculated by using the following equation: $TSM = (W_i - W_f)/W_i \times 100\%$.

2.6.2.2. Color. The color of the films was determined with a colorimeter (CR-400, Konica Minolta co., LTD, Japan). L^* , a^* , and b^* color values were measured in triplicate.

2.6.3. Characterization of structural properties

2.6.3.1. Sulfhydryl groups content. The contents of sulfhydryl groups (SH) were determined according to the methods of Beveridge *et al.*¹⁶ with slight modifications. Briefly, protein samples (60 mg) were dispersed in Tris-glycine buffer (0.086 M Tris, 0.09 M glycine, 4 mM EDTA, pH 8.0) in a blender containing 8 M urea, and mixed by shaking for 24 h at 25 °C. The mixture was then centrifuged at 10 000g for 10 min to obtain the supernatant. Ellman's reagent (4 mg mL⁻¹) was added to the

supernatant. The absorbance of the mixture was determined at 412 nm. A solution without protein was used as blank control.

2.6.3.2. Microstructure. Film microstructure was observed using Hitachi S570 scanning electron microscope at a magnification of $\times 3000$ with an accelerating voltage of 12 kV.

2.7. Statistical analysis

The data are presented as means \pm standard deviation. All experimental data were the average of at least three independent tests. Differences between experimental groups were calculated using Tukey's multiple comparison test. A p -value less than 0.05 was considered statistically significant.

3. Results and discussion

3.1. Structural characterization of the PPI and xylose-modified PPI powder

3.1.1. Degree of glycosylation. Glycosylation is a carbonyl-amino reaction that occurs between the reducing carbonyl end of a sugar and amino acid of protein at a suitable temperature and humidity, which is also known as the Maillard reaction. Numerous previous studies have indicated a significant improvement of the functional properties of products coming from Maillard reaction between polysaccharides and proteins.^{4,17} In order to determine the effect of glycosylation on structural properties of xylose-modified PPI powder, the degree of glycosylation (DG) with different xylose ratio was determined. As shown in Fig. 1, when xylose increases from 1% to 5%, DG is around 6.0% and no significant changes ($p > 0.05$) are observed. A significant linear increase ($p < 0.05$) in DG from 6.0% to 10.7% is observed between 5 and 20% of xylose. It suggests that a threshold level of xylose is required for an effective glycosylation. From this threshold an increased level of xylose may enhance the crosslinking between PPI and xylose through Maillard reaction.

3.1.2. Surface hydrophobicity. Surface hydrophobicity (H_0), an index of the number of hydrophobic groups on the surface of a protein molecule in contact with the polar aqueous environment, is closely related to its functional properties.¹⁵ Generally,

protein films with higher surface hydrophobicity have a better potential to overcome the problem of film solubility and hygroscopy.¹⁸ The index of H_0 for PPI-X power was determined by the fluorescence emission spectra of ANS. As shown in Fig. 2, the surface hydrophobicity of PPI-X is significantly increased from 130.6 to 284.4 (2.2 times higher) with the addition of 1% xylose. The addition of 2% xylose increases surface hydrophobicity by about 2.5 times comparatively to H_0 for the sample without xylose, and the addition of 5% xylose increases this value by 2.7 times. Almost similar trend in surface hydrophobicity was reported in soy protein film crosslinking with transglutaminase¹⁸ and glucomannan.⁹ The observed increase may be attributed to the partial unfolding of protein molecules during the xylose-modified PPI preparation.¹⁸ Thus, the change of protein structure could lead to the exposition of the hydrophobic groups located within the hydrophobic core of proteins, and hence, increase the covalent bond number between xylose molecules and PPI.

3.1.3. FTIR detection of glycosylation reactions. IR spectroscopy would be valuable for detecting the presence of glycosyl groups on proteins.¹⁹ The main absorption peaks are located in the spectral range $3600\text{--}3000\text{ cm}^{-1}$ which are attributed to free and bound O-H and N-H groups.^{20,21} Other bands are observed in the $1700\text{--}1600\text{ cm}^{-1}$ amide I region governed by the stretching vibrations of C=O and C-N groups,²² in the amide II $1600\text{--}1500\text{ cm}^{-1}$ region associated to the N-H bending,^{21,23} and in the range of $1000\text{--}1200\text{ cm}^{-1}$ corresponding to the stretching C-O groups.^{21,24,25}

The FTIR spectra of xylose and PPI glycosylated with different contents of xylose is shown in Fig. 3. It has been reported that the protein in the infrared region had several characteristics absorption band, including amide I ($1600\text{--}1700\text{ cm}^{-1}$) and amide II ($1600\text{--}1500\text{ cm}^{-1}$) which were the most valuable to study secondary structure.^{22,26} All samples exhibit strong IR absorbance at around 1655 cm^{-1} , 1555 cm^{-1} , corresponding to amide I and amide II bands respectively.

The spectra of the xylose and xylose-modified PPI have showed significant different in the $3600\text{--}3000$ and $1200\text{--}1000\text{ cm}^{-1}$, as shown in Fig. 3a. In the $3600\text{--}3000\text{ cm}^{-1}$, free hydroxyl groups have stretching vibration absorption, and in

Fig. 1 Effect of xylose content on the degree of glycosylation of peanut protein isolate different letters (a and b) indicate significant differences ($p < 0.05$).

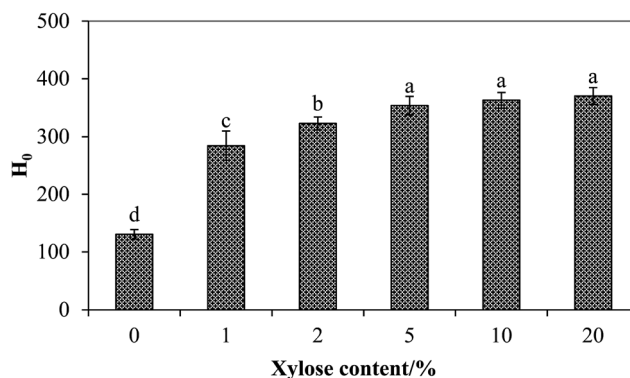

Fig. 2 Effect of xylose content on surface hydrophobicity of peanut protein isolate different letters (a–d) indicate significant differences ($p < 0.05$).

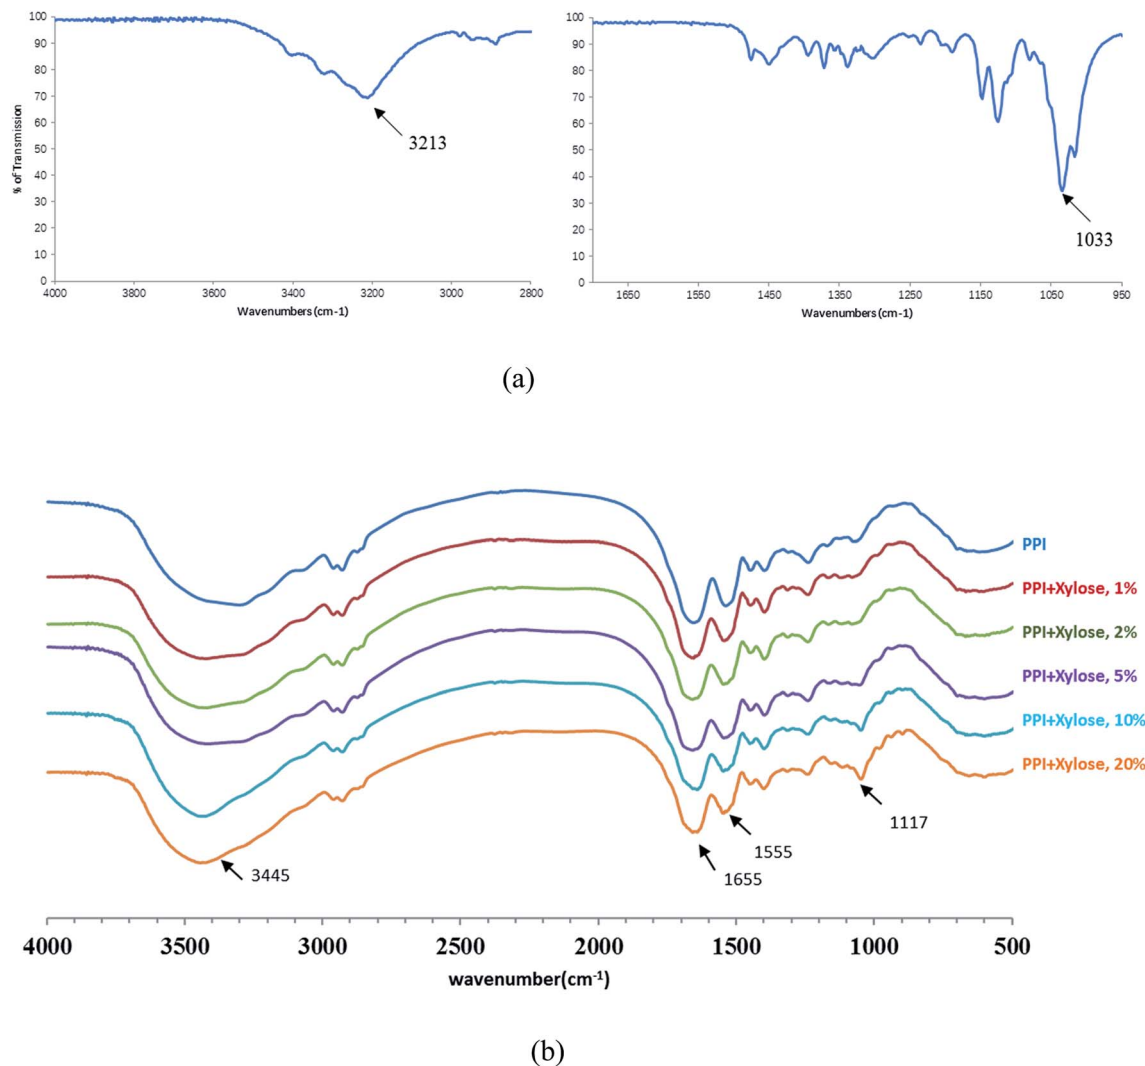

Fig. 3 FTIR absorbance spectra of xylose and xylose-modified PPI glycosylated with different xylose content. (a) xylose; (b) from top to bottom: PPI, 1% xylose, 2% xylose, 5% xylose, 10% xylose, 20% xylose.

the 1200–1000 cm^{-1} stretching vibrations of C–O bond have strong absorption peak. When protein is conjugated with sugar molecules by covalent bond, the increasing hydroxyl content is a typical characteristic. This is expected because the sugars contain OH groups which contribute to an enhanced absorption of the free hydroxyl band.¹⁹ In 3600–3000 and 1200–1000 cm^{-1} , when analyzing the absorption peaks at 3445 cm^{-1} and 1117 cm^{-1} attributed to –OH and C–O groups, we observed that the absorption of xylose-modified PPI is enhanced with xylose increasing, with a particular emphasis at 10% and 20% xylose.

Therefore, a broad absorption band at about 3445 cm^{-1} was observed for composites at xylose level 1–5%, which can be attributed to the overlapping of free and bound O–H xylose and N–H groups coming from the protein. PPI–X composites showed a shift to high wavenumbers, and obviously lower width than PPI, with a particular emphasis at 10% and 20% xylose indicating the presence of O–H groups. This could come from a higher degree of crosslinking between protein and xylose.²⁷

3.2 Mechanical, physical and structural properties of PPI–X films

3.2.1. Mechanical properties. Mechanical properties of biopolymer films, mainly including tensile strength (TS) and elongation (E), are extremely important from a technology point of view, since packaging materials must have adequate mechanical strength to maintain their integrity during handling and storage.¹² To test the mechanical properties of the xylose-modified film, the xylose-modified PPI powder was dissolved in water to form films. PPI–X films showed significantly ($p < 0.05$) higher values of TS, E than the control film PPI, as shown in Fig. 4. Moreover, when the xylose content was increased from 1 to 10%, TS (5.3 MPa) and E (103.0%) gradually increased. However, a further increase of xylose content from 10 to 20% decreases slightly the TS ($p < 0.05$) and E values ($p > 0.05$). Nevertheless, these values remained higher than the control film (Fig. 4). An improvement of TS has also been observed, for peanut protein film glycosylated with gum arabic,

Fig. 4 Effects of glycosylation on mechanical properties of PPI-X film different letters (a–c) and (a'–c') indicate significant differences between the film ($p < 0.05$).

Fig. 5 Effect of xylose content on the solubility of PPI-X film different letters (a–e) indicate significant differences of the film ($p < 0.05$).

and for soy protein film with glucomannan, respectively.^{9,11} A rising xylose content increases film tensile strength and elongation, due to the formation of covalent bond interaction between xylose and protein.⁹ However, such an increase only took place up to 10% xylose, above this value; the increase in xylose content did not produce any increase in tensile strength and elongation, probably due to film matrix saturation with xylose. For 20% xylose, plasticization could be probable with minor effect on stretching ability. This is rather interesting as it is generally considered that increases in TS of protein films are accompanied by decreases in E .¹⁸ The differences of film-forming mechanism by different cross-linking methods may explain the differences of these observations. In the present case of xylose cross-linking, both covalent cross-linkage and non-covalent interactions between protein molecules induced by xylose addition seem to be involved in the film network formation.

3.2.2. Physical properties

3.2.2.1. Film solubility in water. Film solubility can be viewed as a measure of the water resistance and the integrity of a film, is usually required for potentially commercial films. A way to evaluate this resistance is to measure the water solubility which is an indicator of film's hydrophilicity.²⁸ Addition of xylose significantly decreased PPI-X film solubility ($p < 0.05$), while the moisture content of PPI-X films was not changed significantly (in the range of $10.4 \pm 0.9\%$ to $10.86 \pm 0.4\%$) as shown in Fig. 5. Compared to PPI film, a sharply decrease (from 96.6% to 52.6%) of the solubility of PPI-X film was observed with addition of 1% xylose. When the content of xylose varied from 1% to 10%, the solubility of the films continually decreased to 43.4%. When the xylose content reached 20%, the solubility decreased slightly although no significant difference ($p > 0.05$) was found. This decrease in solubility can be attributed to the interactions between protein side chains and exposure of the free sulfhydryl (SH) groups and hydrophobic side chains induced by cross-linking. This observation is in agreement with results presented above, which showed significantly higher values of H_0 and higher degree of graft in the case of films with higher xylose content.

The PPI film dissolves immediately (Fig. 6(1-a)) after immersion in water and is disintegrated into small pieces. Most

of the films (xylose content $> 2\%$) maintain their integrity after incubation in water for 12 h. However, only the 10% and 20% xylose containing films maintained their integrity after the film immersion for 24 h. This indicated that the protein polymer network in presence of 10% or 20% of xylose was highly stable and that probably only small molecules such as small peptides, and non protein material were soluble.²⁹

3.2.2.2. Colour. The colour of a food product makes a great contribution to the consumers' willingness to buy it.²⁸ Thus, to better evaluate the acceptability of PPI-X films, colour parameters L^* , a^* , b^* were analyzed, as well as the total colour difference (ΔE) due to xylose addition was determined. The effect of xylose content on the color of PPI-X films is shown in Table 1. PPI-X films show high lightness (L^* parameter) values, which remains fairly constant, with a slightly decreasing tendency due to addition of xylose. However, an increasing content from 1% to 20% of xylose causes a slight decrease ($p > 0.05$) in the value of redness a^* (2.4–2.7) and b^* (11.8–12.7). The color change of the film is mainly caused by the products coming from Maillard reaction.³⁰ The tendency of increasing values of a^* and b^* was obtained for other protein films containing saccharides.⁹ Taking into account statistical data, the total colour difference (ΔE) is not significantly affected by the addition of xylose, showing that incorporation of xylose in PPI film does not significantly affect the appearance of the food product.

3.2.3. Structural properties

3.2.3.1. Sulfhydryl group content. As it can be seen from Fig. 7, the SH content of all PPI-X films is significantly lower than the one corresponding to xylose-modified PPI powder. The higher SH contents of xylose-modified PPI powder correlates with the lower SH contents of PPI-X films. When the xylose level increases from 1% to 10%, a gradually decrease of SH contents of PPI-X films is observed, and reaches a minimum value of $1.8 \mu\text{mol g}^{-1}$ at 10%. Glycation-induced cross-linking through covalent bonding exposes the free sulfhydryl groups and favors the formation of new disulfide bonds due to the evaporation of solvent during drying step of film formation.³¹ However, when the xylose content is increased from 10% to 20%, SH content of PPI-X film increases ($p < 0.05$). That can be explained by the fact

Fig. 6 Pictorial view of dissolution (solubility) of PPI and PPI-X film. The first, second and third row show solubility of PPI-X film when immersed in water for 0 h, 12 h and 24 h, respectively.

Table 1 Effect of xylose content on the color of PPI-X films^a

Value	Xylose concentration (%)					
	0	1	2	5	10	20
L^*	89.62 ± 0.27^a	89.54 ± 0.55^a	89.29 ± 1.24^a	89.04 ± 1.14^a	89.46 ± 0.78^a	89.12 ± 0.56^a
a^*	2.39 ± 0.19^a	2.52 ± 0.20^a	2.41 ± 0.27^a	2.53 ± 0.29^a	2.54 ± 0.27^a	2.66 ± 0.22^a

that the number of hydroxyl groups of xylose increases, which enhances the absorption of water molecules, and thus constrains the interaction of sulfhydryl groups. It is in agreement with results presented below, which show less compact structures of PPI-X film upon 20% xylose.

Fig. 7 Effect of xylose content on sulfhydryl group content of PPI-X and PPI-X films different letters (a–d) and (a'–e') indicate significant differences between the film ($p < 0.05$).

3.2.3.2 Microstructure. The mechanical and physical properties of protein films are closely related to their microstructural characteristics, which are highly influenced by the film formulation and the manufacturing process. SEM was used to visualize the surface of each film. Imaging of the film structure is useful to understand the film behavior and properties.³² The micrographs of the PPI and PPI-X films are shown in Fig. 8. PPI film displays ridges, valleys, pores and cracks in the cross-section of films. With 1% xylose content, the PPI-X film shows a more smooth structure, but loose lamellar structure, with less pores or cracks. When xylose content increases from 2% to 5%, less loose lamellar in PPI-X films is observed, but pores or cracks are observed. It can explain the gradual improvement of the tensile strength of PPI-X film with increase of xylose content (Fig. 4). When xylose content increased to 10%, the PPI-xylose films become relatively more dense and compact with a reduced film heterogeneity, but little pores can still be observed. It suggests that the dense structure is caused by intermolecular covalent and non-covalent interactions,^{9,11,33} indicating the effectiveness of the glycosylation between PPI and xylose. Anker³² reported that water evaporates resulting in a denser structure with smaller pores. However, when xylose

Fig. 8 SEM micrographs of PPI and PPI-X films, (a) PPI film, (b) with 1% xylose, (c) with 2% xylose, (d) with 5% xylose, (e) with 10% xylose, (f) with 20% xylose ($\times 3000$).

Fig. 9 Mechanism of glycosylation of PPI for film properties improvement.

content reaches 20%, a non-smooth structure with large clumps appears, which is probably due to the formation of more macromolecular polymers.⁹ Since increasing the concentration of reactants could increase the glycosylation yield, it could also result in greater protein denaturation and polymerization/aggregation.^{34,35} So this structure may result in a film with weaker mechanical properties.

3.2.4 Mechanism of glycosylation of PPI for film properties improvement. To elucidate why glycosylation between the peanut isolated proteins and the xylose improves the mechanical and resistant properties of PPI-X film, a correlation analysis between protein structure and film properties was performed. DG, H_0 , sulfhydryl group content of PPI-X have a significant positive correlation with tensile strength and elongation, and expectably have negative correlation with TSM. However, the

sulfhydryl group content of PPI-X film has opposite trends (data not shown). As suggested in Fig. 9, after glycosylation with xylose, protein molecules unfold greatly, exposing the internal hydrophobic and sulfhydryl groups. Then hydrophobic interaction and disulfide bonds were formed in the protein network, which can bear high degree of deformation, resulting in improvement of tensile strength and elongation of the films. Moreover, the exposure of hydrophobic groups weakens the hydrophilicity of protein and enhances the hydrophobicity; improving therefore the water resistance of the protein film.

4. Conclusion

The effect of xylose content on the structural and functional properties of PPI-X films was investigated. PPI-X films has

some superior characteristics, *e.g.*, much higher tensile strength and elongation, lower total soluble mass, as compared to PPI films. The results indicate that the addition of xylose improves the structural and mechanical properties of the film. Compared to PPI, DG and H_0 of xylose-modified PPI increase with increasing xylose content. Different contents of xylose have significant effect on the physical and structural properties of the PPI-xylose films. Presence of xylose until a level of 10% increases the tensile strength and the elongation and decreases the solubility of PPI-X films. Overall results from this study indicate that the film properties improvement obtained by blending xylose with PPI can be attributed to covalent (Maillard reaction) and non-covalent interaction occurring between xylose and PPI. Moreover, glycosylated PPI-X solution could be converted into powder. Glycosylated PPI powder can then be used as material for film production, which enhances the convenience of transportation and storage, and provides more alternatives for peanut protein film production including solution casting, compression moulding and blow moulding. It is also more convenient to scale up to an industrial production. So the films developed in this work are suggested to be suitable for food inside packing, *e.g.* flavoring bag.
