Nonlinear optical properties of metal nanoparticles: a review

Yu-xi Zhang and Yu-hua Wang*

Metal nanoparticles (MNPs) hold great technological promise because of the possibility of engineering their electronic and optical properties through material design. One of the effective methods to fabricate MNPs is ion implantation. In this review, recent results on the nonlinear optical properties of nanoparticles (including copper, silver, gold, and bismuth nanoparticles) doped in various bases have been discussed. Some specific optical nonlinear properties, such as nonlinear refraction, two-photon absorption, and optical limiting, for femtosecond, picosecond, and nanosecond laser pulses have also been covered. In addition to ion implantation, we have summarized several other methods for the preparation of composite materials, and Z-scan has been used to study the nonlinear optical properties of these materials.

1 Nonlinear optical properties

1.1 Introduction

1.1.1 Theory of nonlinear optics. Nonlinear optics is one of the sub-disciplines of modern optics, with an important academic status on a par with laser physics. Nonlinear optics studies involve various kinds of nonlinear effects that occur in the interaction between laser and matter.1,2 The research object of nonlinear optics mainly involves the new phenomena and new effects in the interaction process of strong laser radiation and materials, including an in-depth understanding of the causes and the process regularity and exploration of their possible applications in the current or future development of disciplines. The interaction of a laser with a nonlinear optical material causes a modification of the optical properties of the material system, such that the next photon that arrives realizes a different material.3 Typically, only laser light is sufficiently intense to generate the nonlinear optical phenomena; therefore, the beginning of this research field is often considered to be since the discovery of second-harmonic generation by Franken et al. in 1961,4 one year after the construction of the first laser by Maiman.3 Although the observation of most nonlinear optical phenomena required laser radiation, some classes of nonlinear optical effects were known long before the invention of the laser. The most prominent examples of these phenomena include Pockel’s and Kerr electro-optic effects.5 The theory of nonlinear optics is based on the well-understood theory of linear optics, particularly on the part covering the interaction of light and matter.

Some important formulas describing ordinary optical phenomena often exhibit mathematical linear characteristics. For example, to explain the refractive index, scattering, and birefringence of the medium, an important physical mass-dielectric polarization vector P was introduced, and it was speculated that it had a simple linear relationship with the incident wave field E, that is

\[ P = \chi E \]  \hspace{1cm} (1)

where the coefficient \( \chi \) is the electromagnetism of the medium.

To make a perfect interpretation of the effects of optical secondary harmonics, third harmonic and rectification effects were observed in a series of media. In this regard, it is necessary to speculate that under the action of an intense laser, the dielectric strength of the medium is no longer linearly related to the intensity of the incident light field, but rather a more general power relationship (including the nonlinear component, which is proportional to the high power of the field) must be applied. That is

\[ P = \chi^{(1)}E + \chi^{(2)}EE + \chi^{(3)}EEE + \ldots \]  \hspace{1cm} (2)

where \( \chi^{(1)} \), \( \chi^{(2)} \), and \( \chi^{(3)} \) are the primary (linear), quadratic (nonlinear), and cubic (nonlinear) polarizabilities of the medium, respectively, and in general, they are the coefficients of the tensor form. By substituting the abovementioned expression of the electrode polarization into the Maxwell equation and utilizing a set of nonlinear electromagnetic wave equations with high order wave field strength, multiplier radiation can be generated when a single frequency of light is incident on a particular medium; when a variety of different frequencies of light are simultaneously incident, they can couple with each other through the media; then, a mixed radiation is generated at the new frequency. From the viewpoint of this new nonlinear
electrification effect, some of the effects discovered at this time and some new effects (such as optical parametric amplification and the oscillation effect, the self-focusing effect, and the stimulated scattering effect) discovered later are collectively referred to as nonlinear optical effects.

1.1.2 Application of nonlinear optics. The rapid development of nanoscience and nanotechnology has provided a number of new opportunities for nonlinear optics. A growing number of nanomaterials have been shown to possess remarkable nonlinear optical properties (NOPs); this promotes the design and fabrication of nano and nano-scale optoelectronic and photonic devices. Nonlinear optics is widely used in many fields such as in laser technology, light aspects of communication, information and image processing and storage, and optical computing. Since nonlinear optics has been widely used in these areas, nonlinear optics has a great value and far-reaching scientific significance.

In the last two decades, a variety of studies have been performed on the NOPs of novel materials because of the potential of these materials in optical device applications, and novel materials with enhanced nonlinearities need to be identified. It was thought that many nonlinear effects could only be observed on the bulk scale, but researchers showed that some nonlinear effects could occur at the nano-scale. As is known, nonlinear optical nanomaterials have a potential to enhance the efficiency and extend the applications of this technique in many new device applications such as in the areas of communications, optical devices, biosensors, and imaging. Nanomaterials with large nonlinear responses can be used as contrast agents in nonlinear microscopy, photocatalysis, and optical limiting applications.

In the past two decades, efficient nonlinear optical materials have made significant progress in laser technology, and these materials have large nonlinear optical properties and a fast nonlinear response for various photonic and optoelectronic applications such as laser ablation, pulsed laser deposition, optical communication, optical information processing, and optical data storage and as optical limiters. Optical limiting is one of the most promising practical applications of all nonlinear optical properties and can be used to protect the human eye and photosensitive components of delicate optical instruments from damage caused by intense optical radiation. Optical limiters strongly attenuate a potentially dangerous laser beam while exhibiting a transmittance to low ambient light. Some of the materials used for nonlinear optical limiting applications are GaSe, CdSe, AgAsS3, and LiIO3, which have utility for different applications. In addition, electro-optic crystals, such as LiNbO3, BaTiO3, and KNbO3, have major potential for nonlinear optical limiting applications.

The search for new nanostructured materials is one of the defining characteristics of modern science and technology. New nanostructured materials can be used to fabricate many devices such as new mechanical, electrical, magnetic, chemical, biological, and optical devices. This review summarizes the advances, such as the development of nonlinear optical random metal–dielectric and metal–semiconductor composites based on metal nanoparticles (MNPs) synthesized by ion implantation, made in optical science and technology in recent years. While seeking and developing new technologies for the synthesis of nanoparticles, substantial practical efforts are made to control the size of the MNP. This is because different applications require different optical properties, and the optical properties are determined by the size of the MNP. In this context, ion implantation nanotechnology allows the fabrication of materials with almost any MNP structures, types of metals, and their alloys and opens up a new way for the fabrication of nanomaterials with the required properties. The electromagnetic properties of these composites are very special, and these composites are very different from the ordinary bulk materials because they may become even more important in the drive towards the miniaturization of electronic and optoelectronic components.

Nonlinear optics plays a key role in the realization and development of many photon technologies, and it can be used to process the optical signal information at enhanced speed. Novel nonlinear optical materials with an ultrafast response time, high resistance to bulk and surface laser damage, and low two-photon absorption have been fabricated, and large optical nonlinearities are critical for their implementation in many applications. Nonlinear materials with these characteristics are also widely used in waveguide applications.

With the development of waveguide media with intensity-dependent refractive indices, optoelectronic devices can be converted into all-optical configurations. A huge enhancement of the nonlinear optical response in random media with MNPs is often associated with optical excitation of the surface plasmon resonances (SPR) that are collective electromagnetic modes and strongly dependent on the geometry structure of the composite medium. Therefore, MNP-containing transparent dielectric and semiconductor materials can be effectively used in new integrated optoelectronic devices.

Although both the classical and quantum-mechanical effects in the linear optical response of MNP composites have been studied for decades, the first experimental results on the nonlinear optical effects in MNPs in ruby-glass have been obtained quite recently by Ricard et al. in 1985. The ability to create nonlinear optical elements with MNPs for application in all-optical switching and computing devices has generated significant interest, and consequently, various studies have been directed at the preparation of composite materials. In practice, to make a composite material in the SPR spectral region, a strong linear absorption is required; thus, attempts are being made to improve the concentration of the MNPs. When all the other parameters of the composite are the same, a system with a higher fill factor will have a higher nonlinear susceptibility.

1.2 Z-Scan technique

In 1989, Sheik-Bahae et al. proposed a new method for measuring the nonlinear refractive index of nonlinear optical materials. The method was characterized by high sensitivity and single-beam measurement. Since the test sample is required to move along the direction of the optical axis, the method is referred to as the Z-scan method. In 1990, Sheik-Bahae et al. applied this method to the nonlinear absorption coefficient of
a measurement material. In 1992, Sheik-Bahae et al. proposed a two-color Z-scan method and applied it to measure non-degenerate nonlinear and non-degenerate nonlinear two-photon absorption coefficients. Within a short time period, the Z-scan technology has continuously improved, and it has been tested and studied in other aspects such as thermal lens effects, laser beam quality testing, and Gaussian beam transmission characteristics. Z-Scanning technology has since developed into having a significant practical value among the test methods used in the study of nonlinear optical properties.

1.2.1 The basic device of the Z-scanning method. The basic device of the Z-scanning method and its optical path are shown in Fig. 1, where the drift of a Gaussian beam convergence output travels through the lens L and the smallest section of the beam crosses at the 0 point of the Z axis; O stand for the test object, placed near the 0 of the Z axis, S is the limiting aperture, and D is the photodetector. During the test, the object to be tested moves along the Z axis and records the relationship between the light intensity and Z value changes. The Z-scanning method of the recording device and the test process are not complicated, but this method provides very rich information about the tested object (Fig. 2).

1.2.2 Measurement of the nonlinear refractive index. The power of the incident light and the linear transmittance of the orifice can, respectively, be described as follows:

\[ P(t) = \frac{\pi \omega_0^2 I_0(t)}{2} \]

\[ s = 1 - \exp(-2r_0^2/\omega_0^2) \]

where \( \omega_0 \) is the waist radius of the beam, \( r_0 \) is the radius of the screen, \( L_0(t) \) is the intensity of the light at the focal point, and the normalized transmittance is given by

\[ T(z) = \frac{\int_{-\infty}^{+\infty} P(t) \Delta\varphi_0(t) dt}{\int_{-\infty}^{+\infty} P(t) dt} \]

The phase change of the wave surface at the focal point on the axis is

\[ \Delta\varphi_0 = k \Delta n_0(t) L_{eff} \]

Among them, \( k = \frac{2\pi}{\lambda} \), \( \lambda \) is the laser wavelength, \( L_{eff} = (1 - e^{-\alpha z}) \), \( \alpha \) is the linear absorption coefficient, \( L \) is the sample thickness, and \( \Delta n_0 = \gamma I_0(t) \).

By definition \( \Delta T_{p,V} = T_p - T \), which represents the difference in the normalized transmittance of the peak-valley in the normalized Z-scan curve, when \( \Delta\varphi_0 \leq \pi \)

\[ \Delta T_{p,V} \approx 0.406(1 - s^{0.25})|\Delta\varphi_0| \]

Therefore, according to the obtained Z-scan curve, \( \gamma \) can be obtained using (6) and (7).

1.2.3 Measurement of the coefficient of nonlinear absorption. Optical nonlinear materials tend to have significant nonlinear absorption, and the absorption coefficient of the material can be written as

\[ \alpha(I) = \alpha + \beta I \]

where \( \alpha \) is the linear absorption coefficient and \( \beta \) is the nonlinear absorption coefficient. Then, the normalized transmittance is given by

\[ T(z, s = 1) = \frac{1}{\sqrt{\pi q_0(z, 0)}} \int_{-\infty}^{+\infty} \ln[1 + q_0(z, 0) e^{-\gamma}] d\tau \]

\[ q_0(z, t) = \beta I_0(t) L_{eff}(1 + z^2/\omega_0^2), \text{when } |q_0| < 1, \]

\[ T(z, s = 1) = \sum_{m=0}^{\infty} \left( \frac{-q_0(z, 0)}{m+1} \right)^m \]

When a Z-scan is performed without an aperture, numerical fitting can be conducted on the experimental results according to the abovementioned formula.

2 NOPs of metal ions implanted into various matrices

In many studies, composite materials with MNPs exhibiting nonlinear optical characteristics were fabricated by various methods and then generally studied using lasers operating at frequencies corresponding to the spectral range of the SPR, as shown in Table 1. However, in fact, when novel materials with MNPs are used, their properties should be systematically studied. Hence, to create new materials promising for practical use in laser systems and integral optics and to optimize their characteristics, the nonlinear optical properties of these materials should be studied not only in the SPR spectral region but also at the specific lasers for industry need.

Nowadays, high-speed optical devices require materials with high values of nonlinear optical parameters such as nonlinear refractive index and nonlinear absorption coefficient.\textsuperscript{46} For Cu, with the increasing dose number, the absorption coefficient and the $\chi^{(3)}$ also increases under the same detection conditions, but the synthesis conditions are different. The results of new investigations on the nonlinear optical parameters of composite materials based on an STO matrix with Cu and Tb nanoparticles are presented. They showed that the effective third-order nonlinear susceptibility is real and has a positive sign. DFWM and Z-scan measurements showed that the value of $|\chi^{(3)}|$ increased with an increase in the implantation dose. Moreover, the slow component of the relaxation time increased (from 0.1 to 3.58 units for Cu and from 2.52 to 4.15 for Tb nanoparticles).

Ag was implanted into the matrix of SiO$_2$, and the sample was tested at the wavelengths 532 nm and 1064 nm; the sample tested at the lower wavelength had a lower $\chi^{(3)}$; this indicated that this new structure of metal nanoclusters represented a new aspect for the study of the nonlinear optical response. However, if the synthesis conditions were changed, the nonlinear parameters changed together. Furthermore, experiments showed that the nonlinear absorption properties of the samples were affected after Ar irradiation. The results revealed the large nonlinear absorption properties of these systems, as characterized by the concomitance of saturable and reverse saturable absorption.

The third-order nonlinearity of 72GeS$_2$–18Ga$_2$S$_3$–10CdS chalcogenide glass implanted by Ag ions was studied. The doses for implantation ranged from $1 \times 10^{16}$ to $2 \times 10^{17}$ ions per cm$^2$, and the Ag nanoparticles were observed via AFM measurements. The third-order nonlinear optical parameter $\chi^{(3)}$ was measured by the femtosecond Z-scan technique and showed a maximum value of $7.58 \times 10^{-11}$ esu.

This indicated that the $\chi^{(3)}$ enhancement of the implanted samples was due to the formation of Ag nanoparticles. The relation between the implanted dose and the third-order nonlinearity was associated with the enhancement of the local field inside the particles and the interaction between Ag nanoparticles, which could be useful in the fabrication of optical devices by controlling the implanted doses to control the optical nonlinearity in glasses.

2.1 Nonlinear optical studies of Au

The third-order NOPs of gold nanoparticles implanted into various matrices (Al$_2$O$_3$, ZnO, and SiO$_2$) have been investigated by the Z-scan method. The nonlinear refractive index, nonlinear absorption coefficient, and the real and imaginary parts of the third-order nonlinear susceptibility have been deduced.\textsuperscript{41} According to the results, when the wavelength was between 300 nm and 800 nm, it was clear that the annealing atmosphere could affect the absorption coefficient. The samples annealed in air had a lower absorption coefficient than the sample annealed
in Ar. Regarding the nonlinear optical response, it was found that the isotropic sample exhibited negative and positive nonlinear absorption at the wavelengths of 532 nm and 355 nm, respectively (Fig. 3). The nonlinear coefficients were $\beta = -4 \times 10^{-12}$ m W$^{-1}$ with an irradiance value of $I_0 = 3.1 \times 10^{14}$ W m$^{-2}$ for 532 nm, and $\beta = 1.5 \times 10^{-10}$ m W$^{-1}$ with $I_0 = 3.36 \times 10^{14}$ W m$^{-2}$ for 355 nm. Moreover, the nonlinear refraction was found to be positive for 532 nm with a value of $n_2 = 3.1 \times 10^{-15}$ m$^2$ W$^{-1}$, but it vanished at 355 nm (Fig. 4).

Analysis of the absorption spectra of gold nanoparticles in three matrices showed that the SPR of gold nanoparticles was located in the region of 525 nm for Al$_2$O$_3$, 540 nm for ZnO, and 500 nm for SiO$_2$. The values of the absorption coefficient reported for the matrices under consideration were $3.3 \times 10^{-16}$ cm$^2$ W$^{-1}$ for Al$_2$O$_3$, $9 \times 10^{-15}$ cm$^2$ W$^{-1}$ for ZnO, and $2.24 \times 10^{-16}$ cm$^2$ W$^{-1}$ for SiO$_2$ (ref. 51) at the wavelength of 532 nm. These data were much smaller than those of the composite materials. Thus, it could be concluded that the nonlinear optical response of the composites was derived from the gold nanoparticles.

### 2.2 Nonlinear optical studies of silicon-based materials

Silicon-based optical devices have received significant attention because of their potential application in high-speed signal processing and no-chip communications.$^{51}$ The NOPs of silicon have been studied for a long time and have been subsequently characterized with various different techniques; this has resulted in a large range of reported data.$^{52}$ The accuracies of these studies were quite essential, which were used to characterize the linear coupling and propagation losses. The nonlinear optical properties of silicon have been utilized in the design of modulators, receivers, and filters in optical communication demonstrations with bit rates in the order of 1 Tbits per s (ref. 54) and in real-time A-to-D converters with the sampling rates of several tens of Gbits per s. A major advantage of the silicon photonic devices is that they can be produced efficiently because of the superiority of the mature silicon processing technology that has been extensively developed to permit low-cost, large-volume electronic circuit production. This makes optical devices compatible with the CMOS technology possible for on-chip integration. The high bandwidths, high speeds, and energy efficiency of optical communication circuits allow on-board communication with performances greatly surpassing those of the electronic alternative.$^{53}$

Si and SiO$_2$ multilayers with a dot size of 2.5 nm were prepared, and their microstructures were characterized by cross-sectional transmission microscopy and Raman spectroscopy. A broad photoluminescence band centered at 870 nm was observed. The multi-layer nonlinear optical effect was studied by the Z-scanning technique under the excitation of two laser pulses. Photoluminescence at room temperature was observed at 870 nm; the large Stokes shift between the linear absorption edge and emission band implied that the emission might originate from the recombination of photoexcited carriers via interface states with an energy level inside the gap.$^{55}$

In Table 2, the nonlinear absorption coefficient and nonlinear refractive index of the sample upon changing the excitation pulse time from ps to fs are shown. When the sample was excited by a picosecond laser, it showed saturation absorption with $\beta = -3.1 \times 10^{-6}$ cm W$^{-1}$ and $n_2 = -1.3 \times 10^{-10}$ cm$^2$ W$^{-1}$. The negative nonlinear refraction could be attributed to the free carrier dispersion effect. The saturation absorption can be attributed to the single photon transition process between the valence band and the interface state. However, when the sample was excited by a femtosecond laser, the sample showed reverse saturation absorption with $\beta = 1.1 \times 10^{-7}$ cm W$^{-1}$ and $n_2 = -1.5 \times 10^{-12}$ cm$^2$ W$^{-1}$. The difference in the free carrier density generated by two pulses laser played a great role in the diverse nonlinear response.

A tunable nonlinear absorption and nonlinear refraction response in Si/SiO$_2$ multilayers have been observed during the transition process from the amorphous to nanocrystalline phases under femtosecond excitation at 800 nm by Zhang et al.$^{57}$ They suggested that the two-photon absorption process dominates in the samples mainly containing amorphous Si phases, whereas the phonon-assisted one-photon transition process between the valence band and interface states dominates the nonlinear optical properties in nc-Si/SiO$_2$ multilayers. This suggests that nc-Si/SiO$_2$ multilayers can be applied in highly sensitive photonic devices such as optical switches and Q-switch lasers.

Silicon nanocrystals are widely used in photonics, with their most important characteristics being two aspects: (1) they can be used as a nonlinear material in various devices, e.g., in bistable optical cavities, in waveguide optical mode monitors based on two-photon excited luminescence detection, and in wavelength shifters using four-wave mixing; (2) they can be used as an entropy source for quantum random number generation, which is the key device for cryptography. Quantum size effects change the properties of Si-nc with respect to bulk silicon; this allows enlargement of the phenomenology and the application spectrum of silicon photonics.$^{58}$

### 2.3 Nonlinear optical studies of Ag

Due to their large third-order nonlinear optical properties caused by surface plasmon resonance and the quantum size effect, noble metallic nanostructures embedded on a transparent dielectric matrix have been attracting significant attention.$^{79,80}$ As promising materials for all-optical signal processing devices,$^{61,62}$ Consequently, a few technologies have been developed such as laser ablation,$^{63,64}$ chemical synthesis, ion implantation,$^{65,67}$ and sol–gel methods. The quantum size effect

will make the material show a more excellent performance, different from that of other noble metallic NPs, and silver NPs experience a lower intrinsic loss of plasmonic energy at visible frequencies that gives rise to SPR.\textsuperscript{68} Moreover, in further research, it has been indicated that the shape of the metallic NPs and their dielectric environment determine the surface frequency and consequently the nonlinear optical properties.\textsuperscript{65,69,70}

NF-RGO (non-covalent functionalized reduced graphene oxide) and NF-RGO/Ag-NPs (NF-RGO decorated with various concentration of silver nanoparticles) were prepared by Sakho \textit{et al.}\textsuperscript{71} The open aperture Z-scan technique was used to investigate the nonlinear optics. Tables 3 and 4 show the numerical calculated values of the nonlinear optical parameters at $\lambda =$ 800 nm with femtosecond and $\lambda =$ 532 nm with nanosecond excitation regimes, respectively. The lower optical limiting threshold was attributed to the charge or energy transfer between NF-RGO and Ag-NPs in the NF-RGO/Ag-NP hybrid. In nonlinear optical absorption, the lower the optical threshold value, the better the optical limiting properties.

In the fs regime, $\beta$ was found to increase with the decreasing concentration of AgNPs. The higher the $\beta$ value, the better the OL properties of the corresponding material. In addition, in the fs regime, the samples exhibited the same optical limiting behavior as in the ns regime. The optical limiting thresholds were found to be lower in the fs excitation regime as compared to those in the ns excitation regime. This was attributed to the prominent plasmon band bleaching of AgNPs when excited at 532 nm. Furthermore, the nonlinear optical analyses showed that the optical properties of the NF-RGO/Ag-NP hybrid were size dependent. This finding provided a good understanding of the graphene-based nonlinear materials and also indicated that the as-synthesized materials could be potential candidates for optical limiting applications. Moreover, Li \textit{et al.}\textsuperscript{68} have observed that the nonlinear absorption coefficients significantly depend on the excitation energy and can be modulated by varying the fluence of Ag\textsuperscript{+} ions.\textsuperscript{68}

In the past few decades, the nanostructures of direct band gap semiconductors, such as Si and Ge, have been extensively studied because of their potential applications in nanophotonics, with their main advantage being their compatibility with conventional integrated circuit technology. Amorphous and crystallized Ge nanostructures embedded in an Al\textsubscript{2}O\textsubscript{3} dielectric were synthesized by a vacuum electron-beam co-evaporation method.\textsuperscript{72} A clear blue-shift of the absorption edge and a large third-order nonlinear optical susceptibility due to the quantum confinement effect were observed.

Herein, three samples with different Ge concentrations ([A] Ge/Al\textsubscript{2}O\textsubscript{3} = 1/5, [B] Ge/Al\textsubscript{2}O\textsubscript{3} = 2/5, and [C] Ge/Al\textsubscript{2}O\textsubscript{3} = 5/5) were synthesized, and the thickness was about 200 nm. The band gap of the semiconductor was increased due to the quantum confinement effect, which caused a blue-shift of the absorption band edge and optical luminescence.\textsuperscript{73,74} Moreover, this effect caused an enhancement of the third-order optical nonlinearity. Optical absorption measurements were performed in the visible to near-infrared range at room temperature. Fig. 5 shows the optical absorption spectra of Ge + Al\textsubscript{2}O\textsubscript{3} films on quartz substrates. It was clear that all these samples exhibited a blue-shift of the band gap because the band gap of the bulk amorphous Ge ($\alpha$-Ge) was about 0.9 eV. According to the indirect transition equation,

$$a(h\nu) = a(h\nu - E_g)^2/h\nu$$

(11)

![Fig. 5 Optical absorption spectra of Ge nanocrystals embedded in Al\textsubscript{2}O\textsubscript{3} films on quartz substrates (synthesized at room temperature; thickness: 200 nm).\textsuperscript{72}](image-url)
The third-order nonlinear optical characteristics of sample A were determined by the Z-scan method at a wavelength of 532 nm and a pulse width of 10 ns. The closed aperture plot (Fig. 6(a)) shows a distinct valley-peak configuration typical of the positive nonlinear effects (self-focusing). The nonlinear optical refractive index $n_2$ defined as

$$n = n_0 + n_2I$$

was calculated using the following equation:

$$n_2 \, (\text{m}^2 \text{W}^{-1}) = 1.232 \lambda \tau_0 \Delta T_{P,V}/(1 - s)^{0.25} L_{\text{eff}} E$$

where $n_0$ is the linear refractive index of the samples, $\lambda$ is the wavelength of light, $\tau$ is the laser pulse width, $L_{\text{eff}}$ is the effective thickness, $E$ is the pulse energy at the focal spot, and $\Delta T_{P,V} = 0.72$. Fig. 6(b) shows the normalized open aperture Z-scan transmission for sample A. A symmetric inverted bell-shaped curve can be observed with a minimum at the focus, which indicates a two-photon or multiphoton absorption process.

### 3.2 Melt-quenching technique

Glasses containing metal nanoparticles exhibit an ultrafast electron response within a few of picoseconds, which also have large third-order optical nonlinearities for a large local-field enhancement factor and strong resorption of the surface plasmon.\textsuperscript{75-77} Thus, these materials have been intensively studied in the last few decades as they are widely used in ultrafast all-optical switching, ultrafast imaging, optical telecommunications, signal processing, and so on.\textsuperscript{78-79} Glasses containing metal nanoparticles are generally fabricated by melt quenching, the sol–gel method, sputtering, ion exchange, ion implantation, or femtosecond laser irradiation.\textsuperscript{80-82} It is typically really difficult to control Bi nanoparticles formation in glasses. Thus, Lin et al.\textsuperscript{83} proposed a simple method, whereby they used Al to reduce Bi ions to atomic state Bi, and the atomic or molecular Bi gathered together. Bi grows and forms nanocrystals during the subsequent heat treatment. The Z-scan technique was used to investigate the nonlinear optical properties of the Bi nanoparticle composite glasses.

Typical Z-scan normalized transmittance curves for open and closed aperture measurements of these Bi glasses are shown in Fig. 7. The nonlinear index $\gamma$, nonlinear refractive index $n_2$, nonlinear absorption coefficient $\beta$, and third-order optical susceptibility $\chi^{(3)}$ of all the samples were obtained by applying nonlinear curve fitting, and the obtained third-order optical nonlinearities are shown in Table 5. It can be found that the third-order optical susceptibility $\chi^{(3)}$ increases as the heat treatment temperature increases.

3.3 Nanosphere lithography

A systematic study of the size-related nonlinear optical properties of triangular Au particles was reported, where triangular Au nanoparticle arrays with four sizes (37 nm, 70 nm, 140 nm, and 190 nm) were fabricated on SiO2 substrates using nanosphere lithography. There are many ways, such as chemical methods and sputtering method, to fabricate particles of different sizes. Nanosphere lithography has been developed from natural lithography by Hulteen et al. in 1995 and proven to be a powerful tool to fabricate periodic particle arrays (PPAs) with a tunable shape and size, which has made it possible to quantitatively study the optical properties of nanoparticles (Table 6).

3.4 Organometallic pyrolysis method

In recent years, the NOPs of nanoparticles have attracted significant interest due to their various applications in
optoelectronic and biological fields such as in optical limiting,\textsuperscript{90,91} multiphoton imaging,\textsuperscript{92,93} all-optical switching,\textsuperscript{94,95} cell biology, and cancer-therapy.\textsuperscript{96–98} The combination of nanomaterials and semiconductors has acquired particular interest for basic sciences and technological applications.\textsuperscript{99,100}

In the study reported by Salah \textit{et al.},\textsuperscript{101} Au NPs and nanocomposite of Au–CdSe of different NPs sizes and concentrations were prepared.

The effect of the nanosize of CdSe on the nonlinear absorption was investigated, as shown in Fig. 11. At the excitation intensities $I_0 = 118 \, \text{mJ}$, the transmission via NPs of different sizes increases near the focus beam ($z = 0$). This is an indication that the absorption of the ground state is higher than that of the excited states. The SA decreases as the QDs size increases. This decrease is attributed to the decrease in absorption associated with the increase in the QD size.

The effect of the concentrations of NPs on the nonlinear absorption behavior of NPs was examined, as shown in Fig. 12. OA Z-scan transmissions at a laser energy of 195 \, \text{mJ} (0.31 \, \text{GW cm}^{-2}) were carried out for different concentrations of Au–CdSe at CdSe QDs sized 3.54 nm. The observed SA nonlinear behavior

Table 8: Nonlinear absorption parameters for CdSe:Au at different concentrations\textsuperscript{101}
was found to increase as the concentration of NPs increased. The variation in the calculated nonlinear absorption coefficients of Au–CdSe at different concentrations is summarized in Table 8.

### 3.5 Colloidal chemical synthesis

Among the II–VI semiconductors, CdSe is one of the promising semiconducting materials that has been studied for application in solar cells, thin film transistors, gamma-ray detectors, memory devices, and optoelectronic and biological applications. Polymer nanocomposites (PNCs) are a class of relatively new materials with ample potential applications. Herein, the pure CdSe PNC was marked as sample A. Ag–CdSe hybrid PNC was prepared via a colloidal chemical synthesis technique by mixing the required amounts of Ag colloids with CdSe PNC. The volume fraction of Ag was changed by keeping the volume of CdSe PNC constant. The prepared nanocomposite samples had the composition Ag(x)–CdSe PNC, with x = 0.1, 0.2, and 0.3%, and these samples were marked as B, C, and D, respectively. The nonlinear optical properties of the nanocomposite thin films were investigated using the Z-scan technique with a 2 mW CW He–Ne laser operating at 632.8 nm.

### 4 Conclusions

Nonlinear optics was established soon after the invention of the laser in 1960. It has a long development history of about half a century, and its research field has been continuously developing in depth and breadth. Nonlinear optics studies involve various kinds of nonlinear effects in the interactions between a laser and matter; the research contents include two aspects: one is the study of how to change the macroscopic parameters, such as susceptibility, dielectric coefficient, refractive index, and absorption coefficient, of the matter in the laser with an aim to realize the control of matter by light. The other aspect involves study of how pump-laser-induced matter changes can affect the parameters, such as frequency, power, wave vector,

Thermo-optical coefficient (dn/dT) was calculated using the following relation:

\[
\frac{dn}{dT} = -\frac{\lambda k}{P_a L_{at}} \Delta \varphi_0
\]  

where k is the thermal conductivity (0.09 W cm⁻¹ K⁻¹) and Δ\varphi₀ is the on-axis phase shift. The calculated values of dn/dT are provided in Table 9. The refractive index of the nanocomposites increases with the increasing Ag content. In addition, with the increasing Ag content, the value of dn/dT increases; this indicates that the increased amount of energy absorbed by PNC and hence its nonlinear parameters. The increase in the value of χ(3) for the Ag–CdSe hybrid PNC film as compared to that of the pure CdSe PNC film may be due to the SPR resulting from the doped silver metal, which largely enhances the local field near the particle’s surface. Wang et al. also observed a dramatic increase (eight times) in the n₂ value for Ag/LiNbO₃ as compared to that in pure LiNbO₃ due to the surface plasmon interactions.
