Significantly improved cyclability of lithium manganese oxide, simultaneously inhibiting electrochemical and thermal decomposition of the electrolyte by the use of an additive†

Bo Liao,a Hongying Li,a Xianshu Wang,a Mengqing Xu,ab Lidan Xing,ab Youhao Liao,ab Xiang Liu*ab and Weishan Li*ab

Lithium manganese oxide (LiMn2O4) is one of the most promising cathodes for lithium ion batteries because of its abundant resources and easy preparation. However, its poor cyclability, especially under elevated temperature, limits its application on a large scale. In this work, it is reported that the cyclability of LiMn2O4 can be significantly improved by applying 4-(trifluoromethyl)benzonitrile (4-TB) as an electrolyte additive. Charge/discharge tests indicate that the capacity retention of LiMn2O4 after 450 cycles at 1C and 55 °C in a standard electrolyte, 1 M LiPF6 in EC/EMC/DEC (3 : 5 : 2, in weight), is improved from 19% to 69%. Further electrochemical and physical characterization demonstrates that 4-TB can, on the one hand, be electrochemically oxidized preferentially compared to the standard electrolyte, which generates a protective interphase film on LiMn2O4. On the other hand, 4-TB can effectively combine with protonic impurities, which inhibits the thermal decomposition of the electrolyte. This dual-functionality of 4-TB contributes to the significantly improved cyclability of LiMn2O4.

Introduction

Lithium ion batteries are the most used power sources for electric vehicles due to their high energy density and environmental friendliness compared with other secondary batteries. Cobalt-containing oxides such as LiCoO2 and ferrous phosphates such as LiFePO4 are the mainstream cathodes of commercial lithium ion batteries. However, cobalt is rare on earth and the preparation of ferrous phosphates is complicated, leading to the high cost of currently commercialized lithium ion batteries. To apply lithium ion batteries more widely, it is necessary to reduce the cost of manufacturing lithium ion batteries. Spinel LiMn2O4 is one of the most promising cathodes for lowering the cost of lithium ion batteries, owing to the abundance of manganese and the easy preparation of LiMn2O4. However, the poor cyclability of LiMn2O4, especially under elevated temperature, limits its application in practice, which is caused by the poor compatibility of LiMn2O4 with carbonate-based electrolytes. The carbonate-based electrolytes might be decomposed electrochemical-oxidatively on charged cathode or thermally under elevated temperature. The electrochemical-oxidation decomposition of electrolyte takes place in the form of complexes of solvents with anion PF6−, yielding HF. On the other hand, the electrolyte also suffers thermal decomposition when it is stored under elevated temperature. HF is also generated during the thermal decomposition due to the reactions of LiPF6 with trace protonic impurities in the electrolyte such as H2O. The resulting HF from the electrochemical-oxidative or thermal decompositions causes manganese dissolution of LiMn2O4 or even the corrosion of aluminum (current collector), leading to the poor cyclability of LiMn2O4.

Several methods have been reported to mitigate the electrochemical-oxidation decomposition of the electrolyte, including partially substituting transition metal elements such as Co and Ni for Mn or non-metal elements such as F for O in LiMn2O4 coating LiMn2O4 with inert materials designing LiMn2O4 with special crystal plane, and using electrolyte additives that can help build protective interphase film on LiMn2O4. Comparatively, less attention has been paid to the inhibition of the thermal decomposition of the electrolyte. Previously, we developed a new additive, 4-(trifluoromethyl) benzonitrile (4-TB), to enhance the cyclability of LiNi0.5Mn1.5O4 under 4.9 V (ref. 24) and LiCoO2 under 4.5 V (ref. 25). It was found that 4-TB could combine transition metal ions in cathode and then be oxidized preferentially compared to the solvents.
This preference helps build a protective interphase film that can suppress the electrochemical-oxidation decomposition of the electrolyte. In this work, we report that 4-TB can not only be electrochemical-oxidized preferentially, which helps build a protective interphase film on LiMn$_2$O$_4$, but also coordinates protonic impurities in electrolyte, which mitigates the thermal stability of the electrolyte. This dual-functionality of electrolyte additive has not been reported before in literature and provides a new approach for improving the cyclability of cathodes of lithium ion batteries, not limited to LiMn$_2$O$_4$.

Experimental and calculation

Sample preparation

4-(Trifluoromethyl)benzonitrile (4-TB, >99%) was purchased from Alfa Aesar Technology Co., Ltd. A standard (STD) electrolyte with water content controlled to less than 10 ppm, 1 mol L$^{-1}$ lithium hexafluorophosphate (LiPF$_6$) in a mixed solvent of ethylene carbonate (EC)/ethyl methyl carbonate (EMC)/diethyl carbonate (DEC) (3 : 5 : 2, in weight) was provided by Guangzhou Tinci Materials Technology Co., Ltd., China. These chemicals were used without further purification. The electrolyte containing 4-TB was prepared in an argon-filled glove box (MBraun, Germany), by adding 4-TB into the STD electrolyte. 0.5 wt% 4-TB, which was found to be the optimal additive, was used to improve the cyclability of LiMn$_2$O$_4$.

LiMn$_2$O$_4$ working electrode consists of 80 wt% LiMn$_2$O$_4$ (Hunan Dahua New Energy Co., Ltd., China), 10 wt% conductive carbon (TIMCAL Ltd., Switzerland), and 10 wt% PVDF (Oflourine Chemical Tech Co., Ltd., China). The mixture was coated on aluminum current collector, dried at 120 °C for 8 h, and punched into disks of 1.13 cm$^2$. To ensure the consistency of all the electrodes, the loading of LiMn$_2$O$_4$ in the electrodes were controlled at the level of 1.93 ± 0.01 mg cm$^{-2}$.

Results and discussion

Cycle performances of LiMn$_2$O$_4$ under elevated temperature

Fig. 1 presents the cycle performance of LiMn$_2$O$_4$ electrode in the electrolytes with and without 0.5 wt% 4-TB at 1C under 55 °C. As shown in Fig. 1a, which presents the representative one of five samples for each electrode (Fig. S1†), LiMn$_2$O$_4$ exhibits poor cyclability after cycling in the STD electrolyte: retaining a discharge capacity of only 21 mA h g$^{-1}$ and a coulombic efficiency of 94%, as shown in Fig. 1a. The capacity retention is significantly lower compared to the 5th cycle. Correspondingly, its coulombic efficiency is low (Fig. 1b) and its discharge profile after deep cycling becomes different completely from its initial one (Fig. 1c). This is the main issue that restricts the utilization of LiMn$_2$O$_4$ in practice. The electrochemical-oxidative and thermal decompositions are responsible for this poor cyclability. The electrolyte might be decomposed electrochemically on LiMn$_2$O$_4$ during charge process and thermally under elevated temperature. Both of these decompositions yield HF that causes the manganese dissolution from LiMn$_2$O$_4$, leading to the structural collapse. The continuous discharge capacity decay up to 280h, while the abrupt discharge capacity decay from the 280th cycle can be ascribed to the structural collapse LiMn$_2$O$_4$. When 4-TB is employed, the cyclability of LiMn$_2$O$_4$ is improved significantly, as shown in Fig. 1a. The capacity retention is enhanced to 69%. Compared to the LiMn$_2$O$_4$ cycled in the electrolyte without additive, the LiMn$_2$O$_4$ cycled in the additive...
containing electrolyte shows less capacity decay before the 280th cycle. Most importantly, no abrupt discharge capacity decay is observed for the LiMn$_2$O$_4$ cycled in the additive-containing electrolyte. Correspondingly, the coulombic efficiency of LiMn$_2$O$_4$ cycled in the additive-containing electrolyte remains higher (Fig. 1b) and its discharge profile after deep cycling changes insignificantly (Fig. 1d). It is apparent that 4-TB can inhibit the decomposition of electrolyte and the structural collapse of LiMn$_2$O$_4$.

Various electrolyte additives have been proposed for the cyclability improvement of LiMn$_2$O$_4$, which are usually based on the interphase film generated from the additives.\textsuperscript{21–23} Compared with these additives, 4-TB behaves better for the cyclability improvement of LiMn$_2$O$_4$. For example, applying 3 wt% tripropyl borate yields a capacity retention of only 74% for LiMn$_2$O$_4$ after 200 cycles at 1C under 55 °C.\textsuperscript{27} Comparatively, the capacity retention is 80% by using only 0.5 wt% 4-TB for the LiMn$_2$O$_4$ cycled under the same rate, same temperature and same cycle number. Since the capacity decay of LiMn$_2$O$_4$ under elevated temperature is related to not only the electrochemical-oxidation decomposition but also the thermal decomposition of the electrolyte, the improved cyclability of LiMn$_2$O$_4$ is also attributed to the thermal stability improvement of electrolyte by 4-TB besides of its contribution to the inhibition of the electrochemical-oxidation decomposition of the electrolyte. To confirm these contributions, the interphase film formed from 4-TB and the interaction between 4-TB and electrolyte were identified separately.

**Interphase film formed from 4-TB**

As an effective additive for forming an interphase film that can suppress electrolyte decomposition, it should be oxidized electrochemically on the cathode surface before STD electrolyte. The preferential electrochemical-oxidation of 4-TB can be indicated by its higher highest occupied molecular orbit (HOMO) energy than those of solvents, as shown in Fig. 2a. To further confirm the preferential electrochemical-oxidation of 4-TB, the initial charge/discharge process of LiMn$_2$O$_4$ was analyzed further. Fig. 2b presents the differential capacity (dQ/dV) curve of LiMn$_2$O$_4$ in electrolytes with and without 4-TB during the initial cycle of Fig. 1a. Both electrodes show two apparent redox peaks, which are characteristic of spinel LiMn$_2$O$_4$ for typical lithium insertion/extraction.\textsuperscript{6} Compared with the electrode in the STD electrolyte, the LiMn$_2$O$_4$ in the 4-TB-containing electrolyte shows an additional small oxidation peak before lithium extraction, as shown in Fig. 2b, suggesting that 4-TB can be oxidized on LiMn$_2$O$_4$ during charge process. This oxidation peak potential is about 3.85 V, suggesting that 4-TB is far more easily oxidized during charge process than the solvents in the STD electrolyte, which is usually stable at the potential lower than 4.2 V. The preferential electrochemical-oxidation of 4-TB might help build a protective interphase film that inhibits the electrolyte electrochemical-oxidation decomposition and the structural collapse of LiMn$_2$O$_4$.

Fig. 2c presents the chronocoulometric responses of LiMn$_2$O$_4$ electrodes, which were charged to 4.5 V at 0.1C and then kept at this voltage in the electrolytes with and without 4-TB. As shown in Fig. 2c, the electrode in the STD electrolyte has a large residue current during constant voltage process. Since the electrode is charged at a low rate current and the lithium ions in LiMn$_2$O$_4$ should be extracted completely, the residue current should be attributed to the serious decomposition of the electrolyte. Differently, the LiMn$_2$O$_4$ electrode in the
additive-containing electrolyte has a far smaller residue current, suggesting that the interphase film resulting from the preferential electrochemical-oxidation of 4-TB can effectively inhibit the electrolyte electrochemical-oxidation decomposition.

It can be noted from the peak positions of Fig. 2b that the electrode in the electrolyte without additive is more polarized for lithium insertion/extraction than that in the additive-containing electrolyte. This difference suggests that the interphase film formed from 4-TB is beneficial for the lithium insertion/extraction, which can be indicated by the smaller interfacial impedance of the electrode cycled in the additive-containing electrolyte. Fig. 3 presents the electrochemical impedance spectra of LiMn$_2$O$_4$ electrodes in the electrolytes with and without 4-TB after 1 and 10, 450 cycles. The impedance spectra show a linear relation at low frequencies, associated with Li-ion diffusion, and one or more semicircles at high frequencies, representing interfacial properties including charge transfer and interphase film impedance.\textsuperscript{27,28} It can be found, by comparing the semicircles at high frequencies between two electrodes cycled initially (at the first and 10$^{th}$ cycles), that the electrode cycled in the additive-containing electrolyte has smaller interfacial impedance than that in the STD electrolyte, indicative of the less polarization for lithium insertion/extraction on LiMn$_2$O$_4$ with the interphase film formed by 4-TB. The interfacial impedance of the cells with STD electrolyte (Fig. 3a) increases significantly after cycling, showing the interfacial instability of electrode/electrolyte. This instability results from the products of electrolyte decomposition on LiMn$_2$O$_4$ and the manganese dissolution that causes the structural collapse of LiMn$_2$O$_4$. Differently, the impedance spectra of the cells with 4-TB show less change from initial cycle to the last cycle, as shown in Fig. 3b. Obviously, the application of 4-TB can maintain the interfacial stability of LiMn$_2$O$_4$/electrolyte during cycling under elevated temperature. The interphase film originated from the preferential electrochemical-oxidation of 4-TB can effectively inhibit the electrolyte electrochemical-oxidation decomposition.
oxidation of 4-TB not only suppresses the electrolyte electrochemical-decomposition but also prevents LiMn$_2$O$_4$ from structural collapse. The interphase film formed from 4-TB can be confirmed by TEM. Fig. 4 presents the TEM images of the LiMn$_2$O$_4$ particles from the cycled electrodes in the electrolytes with and without additive, with a comparison of fresh one. Smooth and clean surface can be observed on the fresh particle (Fig. 4a). After cycling in the electrolyte without additive, the particle is covered with thick and inhomogeneous deposit (Fig. 4b), indicative of the electrolyte decomposition during cycling. In the electrolyte with additive, however, a thin and
uniform interphase film can be identified on the particle, as shown in Fig. 4c.

Fig. 5 presents XPS profiles of the LiMn$_2$O$_4$ electrodes in the electrolytes with and without 4-TB after 450 cycles at 1C under 55 °C, with a comparison of the fresh one. The cycled electrodes show their XPS profiles differently from the fresh one. The main compositions of the electrode including PVDF as binder, Mn and O in LiMn$_2$O$_4$, can be obviously identified on the fresh electrode: the significant peaks at 285 and 291 eV in C 1s and at 688 eV in F 1s correspond to PVDF; while those at 530 eV in O 1s and at 643 and 653 eV in Mn 2p correspond to metal-oxide bonds. After cycling, however, the intensities of these peaks are reduced in the STD and additive-containing electrolytes, suggesting that the cycled electrodes have been covered by the electrolyte decomposition products. Comparatively, the reduced magnitude of these peaks is more significant for the electrode cycled in the electrolyte without additive than that cycled in the electrolyte with additive, suggesting that there are more electrolyte decomposition products existing on the electrode cycled in the STD electrolyte. Obviously, electrolyte decomposes continuously on the LiMn$_2$O$_4$ electrode in the electrolyte without additive during cycling process, resulting in the accumulation of the electrolyte decomposition products. In the electrolyte with additive, however, an interphase film is generated from the preferential electrochemical-oxidation of 4-TB and the electrolyte electrochemical-oxidation decomposition is inhibited, resulting in the stronger peak intensities of PVDF and metal-oxide bonds compared with those in the electrolyte without additive.

In fact, the peaks at 290 eV in C 1s and at 532 eV in O 1s, both of which correspond to Li$_2$CO$_3$, and the peak at 56 eV in Li 1s, which corresponds to LiF, can be observed more clearly for the electrode cycled in the electrolyte without additive than that in the electrolyte with additive. Since Li$_2$CO$_3$ and LiF are the main products of electrolyte decomposition, the weaker peaks for Li$_2$CO$_3$ and LiF on the electrode cycled in 4-TB-containing

Fig. 6 Changes in color (a), HF content (b) and GC-MS spectrum (c) of the electrolytes after storage at 55 °C for 72 h. Cyclability of LiMn$_2$O$_4$ electrodes at 0.5C for the first three cycles and at 1C for the subsequent cycles under 25 °C, using the electrolytes after (d) and before (e) storage.
electrolyte confirm that the electrolyte decomposition can be inhibited by applying 4-TB. It should be noted that an unidentified peak near LiF in F 1s spectrum appears for the electrode cycled in the electrolyte with additive, suggesting that F in 4-TB has been incorporated into the interphase film. The element N existing in 4-TB can only be detected in N 1s for the electrode cycled in the electrolyte with additive, confirming that the products from the preferential electrochemical-oxidation of 4-TB has been incorporated into the protective interphase film that inhibits the electrolyte electrochemical-oxidation decomposition and prevents LiMn$_2$O$_4$ from structural collapse.

**Improved thermal stability of electrolyte by 4-TB**

To confirm the effect of 4-TB on the thermal stability of electrolyte, the STD and 0.5 wt% 4-TB-containing electrolytes were stored at 55 °C for 72 h. The photos of the electrolytes before and after storage tests are shown in Fig. 6a. It can be seen from Fig. 6a that the color of the STD electrolyte turns to far brown than that of the electrolyte containing 4-TB, confirming that the electrolyte without additive suffers serious thermal decomposition that can be inhibited to a great extent by applying 4-TB. The composition change of the electrolytes after storage was monitored by acid–base titration and GC-MS analysis, and the effect of the electrolytes after storage on the cyclability of LiMn$_2$O$_4$ was evaluated in coin cell under room temperature. Fig. 6b presents the increased HF concentrations of the electrolytes after storage. Correspondingly to the color change observed in Fig. 6a, there is a significantly increased concentration of HF (4386 ppm) in the STD electrolyte after storage, about two times that in the 4-TB-containing electrolyte after storage (2356 ppm). HF will erode LiMn$_2$O$_4$, leading to the capacity decay of LiMn$_2$O$_4$.

Fig. 6c presents the GC-MS spectra of the electrolytes with and without 4-TB before and after storage at 55 °C for 72 h. Both electrolytes have similar spectra: three main peaks at 11.8, 15.3 and 16.6 min, representing EC, EMC and DEC, respectively, and other minor peaks at 8.7, 12.2, 13.4, 14.9 and 15.7 min, which should be ascribed to the coordination of solvents with ions in electrolytes. In the STD electrolyte, the STD and 0.5 wt% 4-TB-containing electrolytes were stored at 55 °C for 72 h. The photos of the electrolytes before and after storage tests are shown in Fig. 6a. It can be seen from Fig. 6a that the color of the STD electrolyte turns to far brown compared to its fresh one, confirming that the thermal stability of the STD electrolyte has been improved by applying 4-TB. The resulting HF from the thermal decomposition of electrolyte might deteriorate the cyclability of LiMn$_2$O$_4$. Fig. 6d presents the cycle performance of LiMn$_2$O$_4$ electrode in the electrolyte with and without additive after storage at 55 °C for 72 h, the data in which are the representative ones of five samples for each electrode (Fig. S2†). The cycling tests were performed in Li/LiMn$_2$O$_4$ coin cells under 25 °C at 0.5C for the initial three formation cycles and at 1C for the remaining cycles. As shown in Fig. 6d, LiMn$_2$O$_4$ experiences fast capacity decay in the STD electrolyte after storage, showing a capacity retention of only 44% after 200 cycles compared to the 76% of that in the electrolyte containing 4-TB. Comparatively, the cycle performance of LiMn$_2$O$_4$ in the electrolytes before storage (Fig. 6e), which was obtained under the same cycling conditions as Fig. 6d, shows less difference between the STD electrolyte and the 4-TB-containing one. The capacity retention of LiMn$_2$O$_4$ is 90% and 86% after 200 cycles, and 83% and 75% after 550 cycles, for the electrolytes with and without 4-TB, respectively. These analyses indicate that the electrolyte after thermal decomposition deteriorates the cyclability of LiMn$_2$O$_4$. It should be noted that there still exists a difference in cyclability of LiMn$_2$O$_4$ between the electrolytes with and without 4-TB under room temperature (Fig. 6e), which emphasizes the contribution of interphase film formed from 4-TB to the cyclability improvement of LiMn$_2$O$_4$. Therefore, the improved cyclability of LiMn$_2$O$_4$ comes from dual contributions of 4-TB: one is forming a protective interphase film from the preferential electrochemical-oxidation of 4-TB; the other is stabilizing the electrolyte by 4-TB. The latter contribution has never been reported before, and therefore, 4-TB provides a more effective solution to the cyclability issue of LiMn$_2$O$_4$ under elevated temperature than those additives that have been reported before.

Since the thermal instability of the electrolyte results from trace protonic impurities, the improved thermal stability of the electrolyte should be related to the interaction of 4-TB with these protonic impurities. To confirm this interaction, H$_2$O was added into DEC with and without 4-TB and the resulting mixtures were analyzed with GC-MS. The obtained results are presented in Fig. 7. Pure DEC shows its characteristic peak at 16.6 min, as shown in Fig. 7a. When 1 wt% deionized water is added into pure DEC, no significant change in GC-MS spectrum is observed (Fig. 6b), suggesting that there is no interaction between DEC and H$_2$O. When 0.5 wt% 4-TB is added into pure DEC, the characteristic peak of 4-TB appears at 13.4 min, as shown in Fig. 7c. No other peak appears in Fig. 7c, suggesting that there is no interaction between 4-TB and DEC. When 0.5 wt% 4-TB is added into the DEC containing 1 wt% deionized water, however, there appears a new peak at 14.3 min except for the characteristic peaks of 4-TB and DEC, as shown in Fig. 7d. Apparently, there exists an interaction between 4-TB and H$_2$O, which are related to –CN group. The –CN combines proton forming –CNH$^+$, which then combines H$_2$O forming –C(NH)$\cdot$OH$_2^-$ that is finally transformed into –C(NH$_3$)$_2$O, as shown in Fig. 7e. The peak at 14.3 min in Fig. 7d corresponds to the coordinate of 4-TB with H$_2$O.

With the dual functionalities of 4-TB, the dissolution of manganese from LiMn$_2$O$_4$ and aluminum from current collector will be inhibited to a great extent. To confirm these contributions, the LiMn$_2$O$_4$ and lithium electrodes, taken from
the cells after cycling in Fig. 1a, were performed with morphological observations and element analyses. The obtained results are presented in Fig. 8. LiMn$_2$O$_4$ particles with spinel morphology and clean surface can be observed in the fresh electrode, as shown in Fig. 8a. After deep cycling in the electrolyte without additive under elevated temperature, however, LiMn$_2$O$_4$ particles have been covered by thick deposits (Fig. 8b), which mainly result from the electrochemical-oxidation decomposition of the electrolyte. During charge process, the solvents together with PF$_6^-$ in the electrolyte will be electrochemical-oxidatively decomposed, forming deposits such as carbonates and LiF, gases such as carbon oxide and acidic species such as HF.$^{11,13}$ The deposits accumulate on LiMn$_2$O$_4$ as the cycling proceeds, accounting for the thick deposits observed in Fig. 8b. The resulting HF together with that from thermal decomposition of the electrolyte will cause the subsequent dissolution of manganese from LiMn$_2$O$_4$ and final structural collapse of LiMn$_2$O$_4$, as indicated by the arrow in Fig. 8b. Differently, the LiMn$_2$O$_4$ particle on the electrode cycled in the electrolyte containing 4-TB maintains the fresh morphology in Fig. 8a, as shown in Fig. 8c, confirming that a protective interphase film has been generated on LiMn$_2$O$_4$.

Fig. 7 GC-MS spectra of DEC containing H$_2$O and/or 4-TB (a–d) and illustration on the coordination of 4-TB with H$^+$ and H$_2$O (e).
from the preferential oxidation of 4-TB during initial cycling, which inhibits the electrolyte oxidation decomposition and the manganese dissolution. Fig. 8d presents the contents of manganese and aluminum deposited on lithium electrode of the cycled cells. The lithium electrodes were dissolved into 25 mL dilute nitric acid solution, which was then performed with ICP-AES analyses. As shown in Fig. 8d, besides manganese, aluminum can also be detected on the lithium electrode, suggesting that the HF also causes the corrosion of the current collector in LiMn$_2$O$_4$ electrode. The concentration of Mn and Al is 1.3 mg L$^{-1}$ and 0.2 mg L$^{-1}$ for the electrolyte without 4-TB but only 0.5 mg L$^{-1}$ and 0.02 mg L$^{-1}$ for the electrolyte with 4-TB, respectively. It is apparent that serious dissolutions of manganese and aluminum happen from LiMn$_2$O$_4$ electrode in the cycled cell using the electrolyte without additive, which can be inhibited significantly by applying 4-TB.

Fig. 8 shows XRD patterns of the cycled LiMn$_2$O$_4$ electrodes in STD and 4-TB-containing electrolytes at 55 °C, with a comparison of fresh one. The diffractions of fresh electrode are characteristic of spinel LiMn$_2$O$_4$ structure together with the current collector aluminum. After 450 cycles at 55 °C in the STD electrolyte, all the diffraction peaks for LiMn$_2$O$_4$ almost disappear, confirming that LiMn$_2$O$_4$ suffers structural deterioration. By contrast, the LiMn$_2$O$_4$ electrode cycled in 4-TB-containing electrolyte maintains the characteristic diffractions of spinel structure, confirming that the interphase film formed from 4-TB yields an effective protection for the structural integrity of LiMn$_2$O$_4$.

Conclusions

The cyclability of LiMn$_2$O$_4$ electrode under elevated temperature can be significantly improved by applying 4-TB as an electrolyte additive. This improvement is attributed to the dual functionalities of 4-TB. On the one hand, 4-TB can be oxidized electrochemically before the electrolyte oxidation decomposition, forming a protective interphase film on LiMn$_2$O$_4$. On the other hand, 4-TB can coordinate with trace impurities such as...
small alcohol and water that are detrimental to the thermal stability of electrolyte. Therefore, the application of 4-TB can inhibit the formation of HF to a great extent by simultaneously inhibiting the electrochemical oxidation and thermal decompositions of electrolyte, and thus reduce the manganese dissolution from LiMn$_2$O$_4$ and aluminum from current collector, leading to the significantly improved cyclability of LiMn$_2$O$_4$.
