Adsorption sensitivity of graphene decorated with B, N, S, and Al towards HCN: a first-principles study

Qingxiao Zhou,^a *^{ac} Weiwei Ju,^a Xiangying Su,^a Yongliang Yong,^a Xiaohong Li,^a Zhibing Fu^b and Chaoyang Wang^b

The geometric structure, adsorption energy, electronic structure, and magnetic properties of hydrogenated graphene (graphane) with the adsorption of a HCN molecule were investigated by first-principles calculations. Compared with graphane, the adsorption of HCN on H-vacancy defected graphane (VHG) exhibited higher stability, which implied that the H-vacancy improved the sensitivity of graphane. However, the small adsorption energies and large bond distance indicated that the weak adsorption of a HCN molecule on the graphane and VHG substrates was due to physisorption. By introducing dopants (B, N, S, and Al), the activity of graphane was significantly improved. The adsorption of HCN changed to chemisorption on the graphane with dopants. Meanwhile, the opening of band gaps by HCN adsorption can be used as an electronic signal to detect HCN gas. Interestingly, the spin polarized density of states (PDOS) results suggested that the adsorption of HCN on VHG and S-doped VHG exhibited magnetic character and half-metallicity behavior. These results could provide useful information to design gas sensors for HCN or spintronic devices based on graphane.

1. Introduction

The controlling of air pollution is now regarded as an important area and the monitoring of toxic gases by sensors is a great technological challenge.^{1–3} Hydrogen cyanide (HCN) vapor is extremely virulent to human beings and animals, because it inhibits the consumption of oxygen by body tissues.⁴ A small concentration will result in damage to the health of human beings,⁵ and thus it is important to explore effective methods to detect HCN gas. A promising gas sensor usually exhibits some advantages such as fast response time, miniature size, high sensitivity, and low cost.^{2,6,7} Carbon-based materials like graphene present promising potential in the application of gas sensors due to their large surface to volume ratio and relatively high reactivity. Graphene, a two-dimensional sp^2 connected carbon monolayer, has attracted great interest since it was first experimentally synthesized in 2004.^{8–11} Recently, graphene used as gas sensors to detect many molecules has been explored.^{12–16} However, the results indicated that the pure graphene exhibits relative low sensitivity to the gas molecules and the zero-gap restrict its application in some important area like gas sensors. Therefore, the introducing of defects and dopants has

been successfully attempted to improve the interaction between the graphene and adsorbents. In this regard, graphane is a promising compound, which was first experimentally prepared by attaching hydrogen atoms on the graphene in 2009.¹⁷

In graphane, the full hydrogenation of graphene leads the sp^2 hybridization of C–C bond in graphene changed to sp^3 hybridization in graphane. Graphane has been studied in recent past due to its unique electronic and magnetic properties.^{18–22} Although the highly mechanical strength and wide band-gap of graphane add to its excellence in applications, the bonds (C–C and C–H bonds) formed in graphane cause weak activity to adsorbents. However, the sensitivity of graphane can be significantly improved by introducing of H-vacancy, which also induced magnetism in graphane.^{23–28} Berashevich *et al.* investigated the influence of adsorbates on the electronic and magnetic properties of graphane, and they found that H vacancies significantly improved the chemical reactivity of graphane to environment.²³ Islam *et al.* investigated the sensing aptitude of graphane by crafting with H-vacancy and dopants, and the results suggested that interaction of graphane towards CH_4 gas molecules was enhanced by introducing H-defect and dopants.²⁹ Therefore, it is worth investigating the sensitivity to gas molecules of graphane with defects and dopants.

In this work, we systematically investigated the geometry, adsorption stability, electronic and magnetic properties of HCN adsorption on graphane. The modified graphane substrates considered here were pure, H-defected, and doped graphane, and the dopants were B, N, S and Al. We hope our study provides

useful information to the application based on graphane for gas sensing.

2. Computational methods and model

All the DFT calculations were performed by the Dmol³ code.³⁰ We used the generalized gradient approximation (GGA) for exchange-correlation functional, as described by Perdew–Burke–Ernzerhof (PBE).³¹ Basiuk *et al.* reported that PBE functional along with Grimme dispersion correction can be suggested as the most suitable for theoretical studies of the interaction between molecules and graphane.³² Therefore, the all results were obtained with Grimme-corrected PBE. We selected DFT semicore pseudopotential (DSSP) to replace core electrons as a single effective potential.³³ A double numerical plus polarization (DNP) was employed as the basis set. The DNP basis set corresponds to a double- ζ quality basis set with a p-type polarization functions to hydrogen and d-type polarization functions added to heavier atoms, which was comparable with the Gaussian 6-31G (d, p) basis set and exhibited a better accuracy.³⁴

We applied $5 \times 5 \times 1$ supercell with periodic boundary condition on the x and y axes to model the infinite graphene sheet. The vacuum space of 20 Å was set in the direction normal to the sheets to avoid the interactions between periodic images. A $15 \times 15 \times 1$ mesh of k -point and the global orbital cutoff of

5.0 Å were set in the spin-unrestricted calculations. All atoms are allowed to relax. Convergence in energy, force, and displacement were set at 2×10^{-5} Ha, 0.004 Ha Å⁻¹, and 0.005 Å, respectively.

We analyzed the adsorption of HCN on hydrogenated graphene (HG). The adsorption energy was obtained from the expression

$$E_{\text{ads}} = E(\text{HCN/HG}) - E(\text{HG}) - E(\text{HCN})$$

where $E(\text{HCN/HG})$ is the total energy of HCN molecule adsorbed on hydrogenated graphene, $E(\text{HG})$ is the total energy of the HG, and $E(\text{HCN})$ is the total energy of a free HCN molecule, respectively.

3. Results and discussion

3.1 Structures of HG, VHVG, BVHG, NVHG, SVHG, and AIVHG

At first, we considered the optimized geometries of the graphene (HG) and H-vacancy defected graphene (VHG), and the relaxed structures were shown in Fig. 1. In the HG, the bond lengths of C–C and C–H were 1.496 Å and 1.109 Å, which was in accord with previous report.³⁵ The H-vacancy was created by removing an H atom from the perfect hydrogenated graphene. Experimentally, the appearance of H-vacancy is very common during the synthetic process, while the graphene is exposed in the hydrogen plasma. After fully relaxation, the C_v atom, which lost a H atom, exhibited unpaired localized electron due to the

Fig. 1 The optimized structures of (a) HG, (b) VHG, (c) BVHG, (d) NVHG, (e) SVHG, and (f) AIVHG.

appearance of H-vacancy. As shown in Fig. 1b, the C_v was labeled. The calculated results indicated that the bond length of C-C around the C_v atom decreased to 1.469 Å, which was consistent with previous literatures.^{25,29}

According to previous results, the appearance of H-vacancy increased the activity of graphane, and the C_v site exhibited high sensitivity towards foreign atoms or molecules. Thus, we considered the introducing of dopants to VHG, and the dopants included B, N, S, and Al atoms. The optimized doped configurations were performed in Fig. 1c-f. Furthermore, the calculated

results suggested that the binding energies of B, N, S, and Al were 2.80 eV, 2.23 eV, 2.55 eV and 3.37 eV, respectively. The calculated E_b were larger than their cohesive energies, which enhanced the stability of the geometry. To explore the influence of H-vacancy and dopants on the graphane, we performed the band structures of the configurations in Fig. 2, and the spin-up (majority) and spin-down (minority) bands were separated in each case. For HG (Fig. 1a), both band structures were symmetrical, and the band gap was 3.686 eV, which was in agreement with the results of Leenaerts *et al.*³⁶ and Islam *et al.*²⁹

Fig. 2 The band structures of (a) HG, (b) VHG, (c) BVHG, (d) NVHG, (e) SVHG, and (f) AIVHG.

In the case of VHG, the majority and minority bands were mismatched and the band gap decreased to 1.704 eV, which indicated that the structure exhibited net magnetic moments. The appearance of H-vacancy released the p electron on the C atom of the graphane and formed a localized state possessing the $0.995 \mu_B$, which induced nonzero magnetization and was consistent with the result of Berashevich *et al.*²³ Furthermore, the spin-up bands showed metallic and the spin-down bands exhibited semiconductivity generating a half-metallic character in the band structure of VHG. After the introducing of dopants, the BVHG, NVHG, and AlVHG were nonmagnetic, which were resulted from the unpaired electron of dopants interacted with the localized electron of C_v atom. Moreover, the band gaps for the BVHG, NVHG, and AlVHG were 2.68 eV, 1.056 eV, and 2.296 eV, respectively. In the case of SVHG, the Fermi level located within the conduction bands in the spin-down bands, while the spin-up bands maintained a band gap of 2.78 eV. Namely, a half-metallic behavior was observed. All in all, the impurity bands appeared around the Fermi level in the doped systems, and then the activity of graphane substrate was expected to be improved to interact with adsorbents.

3.2 Adsorption of HCN on HG and VHG

First, the adsorption of HCN molecule on the surface of HG and VHG were investigated. In order to explore the most stable adsorption structure, the initial adsorption structures for HCN molecule were considered as follows: the H atom close to graphane with the HCN molecule perpendicular to the surface (H site), the C atom close to graphane with the HCN molecule parallel to the surface (C site), and the N atom close to graphane with the HCN molecule perpendicular to the surface (N site). The optimized adsorption systems of H-HCN/HG, C-HCN/HG, and N-HCN/HG were performed in Fig. 3. Meanwhile, for the "C site" in VHG, the C atom of HCN molecule was close to the C_v atom of VHG. After optimization, the adsorption structures of HCN on VHG were also showed in Fig. 4. Furthermore, the calculated bond lengths of HCN molecule, adsorption distance between the HCN and the graphane, and the adsorption energy were summarized in Table 1. In the cases of HCN/HG, the adsorption energies were -0.019 eV, -0.021 eV, and -0.011 eV, respectively. Compared with HCN/HG, the

Fig. 3 The optimized structures of (a) H-HCN/HG, (b) C-HCN/HG, and (c) N-HCN/HG.

Fig. 4 The optimized structures of (a) H-HCN/VHG, (b) C-HCN/VHG, and (c) N-HCN/VHG.

Table 1 Summary of the results for the HCN molecule adsorbed on pure graphene (HG) and H-vacancy defected graphene (VHG). The properties listed are as follows: the distance between the H and C atom of HCN molecule (d_1), the distance between the N and C atom of HCN molecule (d_2), the distance between the molecule HCN and graphene surface (d_{M-G}), the adsorption energy (E_{ads})

System	Site	d_1 (Å)	d_2 (Å)	d_{M-G} (Å)	E_{ads} (eV)
HCN/HG	H	1.078	1.163	3.239	-0.019
	C	1.077	1.163	3.207	-0.021
	N	1.076	1.162	3.686	-0.011
HCN/VHG	H	1.087	1.163	3.583	-0.048
	C	1.077	1.162	2.568	-0.088
	N	1.076	1.162	3.794	-0.027

adsorption of HCN molecule on VHG exhibited higher stability. The results indicated that the C-HCN/VHG was the most stable system, of which the E_{ads} was -0.088 eV. The larger adsorption energies indicated that the appearance of H-vacancy in graphene improved the activity of graphene substrate. For the two adsorption substrates, the "C site" systems exhibited most stability than the other two adsorption structures. However, the relative large adsorption distance and small adsorption energies showed that the interaction between the HCN molecule and the HG and VHG surface were physisorption.

Fig. 5 The optimized adsorption structures of (a) HCN/BVHG, (b) HCN/NVHG, (c) HCN/SVHG, and (d) HCN/AVHG.

3.3 Adsorption of HCN on BVHG, NVHG, SVHG, and AlVHG

According to the discussion in 3.2, for the adsorption of HCN on HG and VH, the initial adsorption system for “C site” was the most energetically favorable system. Thus, we set the HCN molecule parallel to the doped graphene (BVHG, NVHG, SVHG, and AlVHG) with the C atom close to the dopants in the adsorption configurations. The optimized configurations of HCN/BVHG, HCN/NVHG, HCN/SVHG, and HCN/AlVHG were shown in Fig. 5. Furthermore, the corresponding parameters detailedly describing the adsorption systems were summarized in Table 2. As shown in Fig. 5, the HCN molecule did not maintain the linear bond structure after interacting with the doped graphene. The bond lengths of C atom of HCN molecule and the dopants were 1.406 Å, 1.381 Å, 1.796 Å, and 1.867 Å for the adsorption complexes, respectively. As performed in Table 2, the HCN/NVHG exhibited the largest E_{ads} with the value of -1.144 eV. Meanwhile, the adsorption energies varied from -0.115 eV to -1.144 eV, which were all larger than that of HG and VH. The results suggested that the introducing of dopants (B, N, S, and Al) improved the sensitivity of graphene to HCN gas molecules. Moreover, the charge transfer of HCN molecule was analyzed by Hirshfeld method which seems to be more reliable and yield chemically meaningful charges in comparison with Mulliken method.^{37,38} Take the case of HCN/NVHG as example, the N-dopant accepted 0.359 e and the HCN molecule lost 0.125 e, which indicated that some electrons transferred from HCN molecule and graphene substrate to the N-dopant, illustrating

that the dopants can facilitate the interaction between the HCN molecule and the graphene substrate.

As shown in Table 2, we calculated the band gaps of the adsorption systems. The adsorption of HCN induced a band open to the configurations. In case of NVHG, the band gap changed from 1.056 eV to 2.426 eV by the interaction with the HCN molecule. For other cases, the band gaps of BVHG (2.268 eV), SVHG (0.020 eV), and AlVHG (2.296 eV) increased to 2.400 eV, 0.821 eV, and 2.406 eV, respectively. It is well known the change of E_g induces the electric conductivity change of graphene substrate according to the following equation:³⁹

$$\sigma \propto \exp\left(\frac{-E_g}{2kT}\right)$$

where σ is the electric conductivity of the configurations, k is the Boltzmann's constant, and T is the thermodynamic temperature. Therefore, the change of conductance of graphene substrate can be seen as signal to detect HCN gas molecules.

Moreover, the adsorptions of H_2O and NO_2 molecules on the modified graphene substrates were investigated, aiming to explore the selectivity of the structures used as sensors to detect the HCN gas. The most stable final adsorption configurations were performed in Fig. 6 and 7. The adsorption energies of the H_2O molecules on BVHG, NVHG, SVHG, and AlVHG were -0.012 eV, -0.030 eV, -0.007 eV, and -0.025 eV, respectively. The interaction distances were labeled in Fig. 6. According to the calculated results, the small adsorption energies and large bond distances indicated that the adsorption were physisorptions. Furthermore, the modified substrates were slightly changed by the adsorption of H_2O molecule. Compared with the case of HCN, the presence of H_2O molecules cannot interfere in the detection of HCN.

The most stable structure of the NO_2 adsorption systems was NO_2/AlVHG , and the E_{ads} was -0.105 eV and the band gap changed by 0.076 eV. The interaction was somewhat strong, though the change of band gap was smaller than the case of HCN. Therefore, we think that the presence of NO_2 gas molecule may interfere in detecting of the HCN gas.

Table 2 Summary of the results for the HCN molecule adsorbed on VH with dopants (B, N, S, Al). The properties listed are as follows: the distance between the H and C atom of HCN molecule (d_1), the distance between the N and C atom of HCN molecule (d_2), the bond length of C_v atom and the dopant (d_3), the distance between the molecule C atom of HCN molecule and dopant (d_4), the adsorption energy (E_{ads}), the band gap of adsorption system (E_g), and the charge transfer of the HCN molecule (Q)

System	d_1 (Å)	d_2 (Å)	d_3 (Å)	d_4 (Å)	E_{ads} (eV)	E_g (eV)	Q (e)
HCN/BVHG	1.095	1.315	1.575	1.406	-1.040	2.400	-0.121
HCN/NVHG	1.093	1.258	1.496	1.381	-1.144	2.426	0.125
HCN/SVHG	1.101	1.254	1.896	1.796	-0.115	0.821	-0.036
HCN/AlVHG	1.090	1.300	2.015	1.867	-0.412	2.406	-0.394

3.4 Electronic properties

To gain more insight into the effect of the H-vacancy and dopants on the adsorption of HCN molecule on the graphene,

Fig. 6 The optimized adsorption structures of (a) $\text{H}_2\text{O}/\text{BVHG}$, (b) $\text{H}_2\text{O}/\text{NVHG}$, (c) $\text{H}_2\text{O}/\text{SVHG}$, and (d) $\text{H}_2\text{O}/\text{AlVHG}$.

Fig. 7 The optimized adsorption structures of (a) NO_2/BVHG , (b) NO_2/NVHG , (c) NO_2/SVHG , and (d) NO_2/AVHG .

we investigated the change of electronic structures by performing the total density of states (TDOS) and spin polarized density of states (PDOS) of the adsorption complexes in Fig. 8–13. As shown in Fig. 8 and 9, the DOS showed that the HCN/HG exhibited nonmagnetic, while the HCN/VHG exhibited magnetic characters. The PDOS of C_v atom in Fig. 9a showed

that the H-vacancy induced the localized electron of C_v showed a obvious half-metallic behavior and complete spin-polarized states around the Fermi level. The PDOS plots was consistent with the band structures of VHG performed in Fig. 2b, which implied that the appearance of H-vacancy produced significant change in the electronic and magnetic properties of HG.

Fig. 10 The PDOS of configurations of (a) HCN/BVHG and (b) HCN molecule.

Fig. 11 The PDOS of configurations of (a) HCN/NVHG and (b) HCN molecule.

Furthermore, a few overlaps between the HCN molecule and the HG and VHVG substrates, which indicated that the interaction were very weak.

As performed in Fig. 10a–13a, a large area of hybridization between the dopants (B, N, S, Al) and the C_v atom was observed below and above the Fermi level. It was well agreement with the

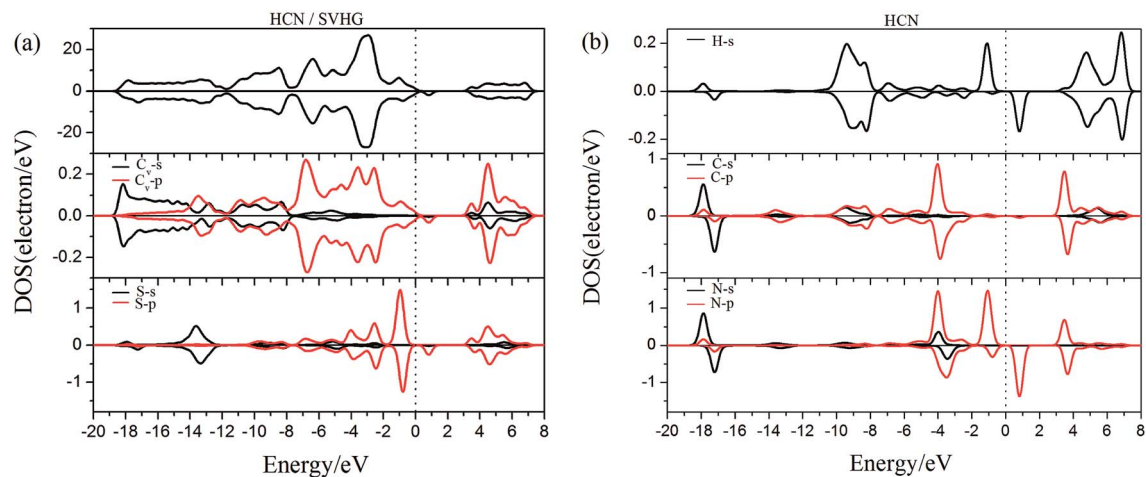

Fig. 12 The PDOS of configurations of (a) HCN/SVHG and (b) HCN molecule.

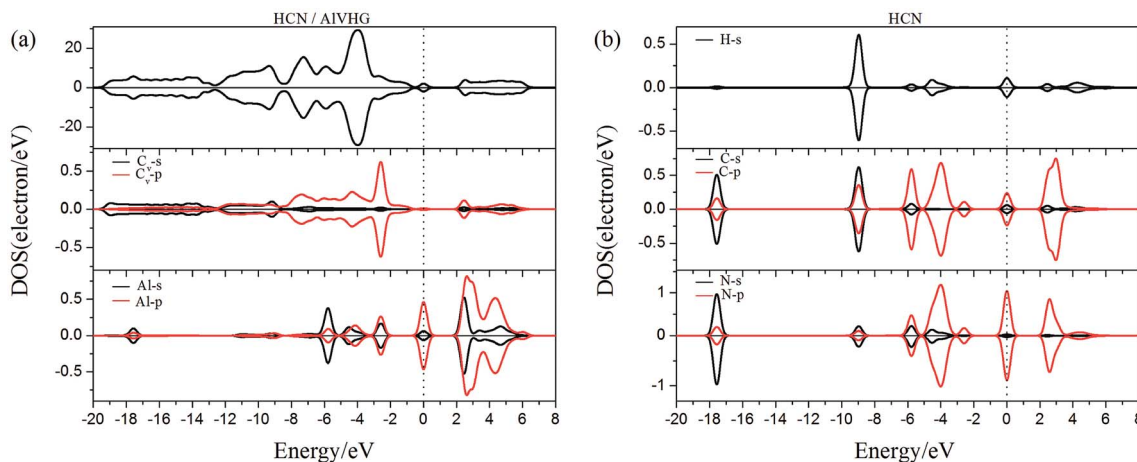

Fig. 13 The PDOS of configurations of (a) HCN/AIVHG and (b) HCN molecule.

large binding energies of the VHGs for the dopants and chemical bonds were formed between the dopants and C_v atom. Furthermore, the HCN/BVHG, HCN/NVHG, and HCN/AIVHG exhibited nonmagnetic according to the symmetry of spin channels, while the HCN/SVHG exhibited net magnetic moment. Compared with the structures without adsorbing HCN molecules, the results suggested that the adsorption of HCN hardly influence the magnetic character of the VHGs with dopants. In the case of HCN/NVHG, the most stable adsorption complex, the obvious hybridization between the N-2p orbital of substrate and C-2p orbital of HCN molecule below the Fermi level indicated that their strong interaction, which was responsible for the large adsorption energy of HCN molecule. As shown in Fig. 12, the spin-up and spin-down channels of HCN molecule became asymmetric and then the HCN/SVHG configuration exhibited magnetic property with the net moment of $0.998 \mu_B$. Furthermore, the spin-down channel exhibited nearly zero-gap semiconductivity, while the spin-up channel showed non-zero DOS at the Fermi level. The result indicated that the HCN/SVHG system maintained the property of half-metallicity. Based on the above discussions, the HCN molecule on the doped HG exhibited higher adsorption stability than that of HG and VHGs. The PDOS plots indicated that the large hybridization between the HCN molecule and dopants, which meant that the strong adsorption of HCN on the doped substrates.

4. Conclusions

Based on the first-principles calculations, we investigated the stable structures of hydrogenated graphene (graphane) doped with B, N, S, and Al, which used as potential gas sensing device to detect HCN molecules. The results indicated that the appearance of H-vacancy improved the activity of graphane and induced a half-metallicity behavior. However, the weak interaction between the HCN molecule and the HG and VHGs substrates illustrated the adsorption was physisorption. After introducing the dopants, the chemical bonds formed between the dopants and the C_v atom. Moreover, the PDOS results

suggested that the impurity peaks appeared around the Fermi level, which indicated that the dopants improved the sensitivity to adsorbents. The large adsorption energies and small bond distance indicated that the adsorption of HCN on doped HG substrates transferred into chemisorption. Furthermore, the adsorption of HCN induced a band gap open on the BVHG, NVHG, SVHG, and AIVHG systems, which could change the conductance of configurations. Therefore, the controlling of electronic and magnetic properties of graphane by the adsorption of HCN molecules is expected to provide meaningful approach for designing HCN gas sensing device.
