Synthesis of Ni/Co/Al-layered triple hydroxide@brominated graphene hybrid on nickel foam as electrode material for high-performance supercapacitors†

Maher Jabeen,‡ Muhammad Ishaq,  ‡ Weiming Song,* Liyang Xu and Qigang Deng*

The determined need for a sustainable energy economy has evoked the increasing interest of researchers concerning the discovery of smart material designs of layered double hydroxide (LDH) nanocomposites for energy-based applications. This paper presents a novel method for the direct growth of brominated graphene and layered triple hydroxide (LTH) on 3D nickel foam (NF) as a supercapacitor electrode by a facile one-step *in situ* crystallization hydrothermal method. Subsequently, the as-synthesized NCA-L@BG-NF hybrids were characterized by TEM, SEM, HRTEM, XRD, FT-IR, RAMAN, XPS, and EDS. Moreover, the electrochemical performance disclosed that by fine-tuning the Ni/Co/Al mole ratios, it was possible to obtain optimized ratio of NCA-L@BG-NF-3 to display the maximum specific capacity of 1998 C g⁻¹ at 6 A g⁻¹, excellent rate capability of 75.3% at 20 A g⁻¹, and excellent cyclic stability of ~91% capacitance retention after 2000 cycles at 20 A g⁻¹ with 100% coulombic efficiency. Furthermore, the greater electrochemical performance of LTH was achieved and synergistically strengthened with a high surface area provided by the conducting brominated graphene oxide framework directly grown on a 3D porous NF to form a binder-free electrode, which could improve the electrochemical performance in terms of charge transport and storage. Accordingly, these remarkable properties show that NCA-L@BG-NF-3 may be considered as a promising candidate for high-performance supercapacitor applications.

1. Introduction

Recently, considerable attention has been paid to the continuously increasing global energy needs and the limited availability of fossil fuels as well as the exploration of renewable energy and of high-performance energy storage systems, such as batteries,¹ fuel cells,² and supercapacitors (SCs).³ In this regard, layered double hydroxides (LDHs) have been gaining importance in recent years. In particular, they are considered as unusual layered materials and a class of lamellar compounds⁴ consisting of positively-charged hydrotalcite-like layers with a weakly bound charge compensating the anions in the interlayer region,⁵ which have potential as positive electrode materials.⁶ LDHs normally have the general formula [M^{II}_{1-x}M^{III}_x(OH)₂]^{x+}[Aⁿ⁻]_{x/n}·mH₂O, where M^{II} and M^{III} denote the layers of divalent and trivalent metallic cations, respectively, and Aⁿ⁻ is an interlayer anion, which can be almost any organic or inorganic anion.⁷ Moreover, due to the layered structure in

LDHs, they usually possess a high specific surface area, which can facilitate fast ion transfer. This offers them great superiority in many electrochemical fields.⁸ However, the electrochemical performances of LDHs are hindered by their low power density, poor electrical conductivity, low mechanical stability, and poor cycle life.⁹ To overcome these limitations and to maximize the capacitance, an efficient incorporation of a versatile class of nanomaterials with a substantial amount of active sites for ion and electrolyte transport in redox reactions is highly favorable.¹⁰ In this regard, materials such as activated carbon, carbon nanotubes (CNTs), graphene, and graphene oxide (GO) with large surface area, high electrical conductivity,¹¹ and excellent electrochemical stability have been used to hybridize with LDHs.¹² However, previous studies have fallen short of examining the LDH hybridized with halogenated graphene grown directly on nickel foam for improving the electrochemical behavior.

Several studies have suggested using brominated graphene (BG), which is a type of graphene derivative obtained through the direct structural transformation of C–C bonds of graphene from sp² to sp³ configuration. This is an efficient strategy to create derivatives of graphene, in which bromine atoms are functionalized on carbon nanosheet skeletons covalently.¹³ The literature on BG shows a variety of approaches to achieve BG.

Jankovsk *et al.* discussed the properties of graphene that could be tailored through chemical modifications, such as hydrogenation or halogenation. The halogen-based chemically modified graphene material exhibited many unique properties. Brominated graphene is a highly favorable starting material for the synthesis of other graphene derivatives due to the highly reactive C–Br bonds.¹⁴ Nevertheless, to the best of our knowledge, almost no studies have been centered on the hybridization of BG with LDHs. Peng *et al.* synthesized fluorinated graphene/Co–Al–LDH composites as electrode materials for supercapacitors, which exhibited the highest specific capacitance of 1222 F g^{−1} at 1 A g^{−1} and the best rate capability.¹⁵ Wu *et al.* reported a hybrid structure consisting of a chemically converted graphene-encapsulated carbon@nickel–aluminum LDH high-energy supercapacitor, which could deliver a high energy density of 35.5 W kg^{−1} at 670.7 W kg^{−1} power density at 1 A g^{−1} with an excellent rate capability.¹⁶

On the other hand, LDH powder, which is usually used for binder-enriched electrodes prepared by the conventional slurry-coating technique, has been mixed with a conducting agent and binder and then coated on nickel foam (NF) to form electrodes.^{17,18} Consequently, the addition of a polymeric binder reduces the inclusive performance of the SCs by hindering the charge transport rate and increasing the total mass of the electrode. However, the tedious preparation steps have a great influence on the electrochemical performance. In addition, the contact and electrical conductivity between the LDH and NF are poor. In this context, modern research has focused on growing LDHs with interconnected architecture directly on a conductive substrate to form a binder-free electrode for supercapacitors, which could act as a promising substrate in LDH-based SCs. This is because the such an architecture can reduce the intensive accumulation of LDH, allowing maximum use of the active materials, while the 3D porous NF provides more channels to facilitate rapid penetration of the electrolyte ions into the active LDH materials of the electrodes compared to that achievable with the common slurry-coating technology.^{19,20}

Inspired by the above findings, in this study, we explore the possibility of loading BG layers onto the surface of Ni/Co/Al–LTH, which in turn can be grown directly on NF as a binder-free SC electrode by a one-step *in situ* crystallization hydrothermal method. Compared with pure NCA-L and NCA-L@G–NF, the electrochemical performance reveals that by fine-tuning the Ni/Co/Al mole ratio, the optimized ratio of NCA-L@BG–NF-3 hybrid exhibited the highest specific capacity. These impressive results revealed a great promise for application of the NCA-L@BG–NF-3 hybrid in SCs, which could achieve the best rate capability and the most stable capacitance retention, making it one of the most promising electrode materials for SCs.

2. Experimental section

2.1 Materials and chemicals

Natural graphite powder (<45 μm, ≥99.99%), concentrated sulfuric acid (H₂SO₄, 98.08%), sodium nitrate (NaNO₃), hydrogen peroxide (H₂O₂, 30%), and potassium permanganate

(KMnO₄) were used to synthesize the GO. Ni(NO₃)₂·6H₂O, Al(NO₃)₃·6H₂O, CoCl₂·6H₂O, urea, ethanol (~99.5%), HCl, and nickel foam were used to synthesize the LTH–NF. For the bromination of GO, HBr was used. All the chemicals were obtained from Sinopharm Chemical Reagent Co. Ltd (Shanghai, China). All of the materials were without further purification. All the solutions were prepared using Milli-Q water (18.25 MΩ cm resistivity) as the solvent.

2.2 Preparation of GO and suspension of BGO

Graphene oxide (GO) was synthesized according to Hummers method reported in our previous study.²¹ The brominated graphene oxide suspension (BGO) was prepared from the as-prepared GO in the following typical procedure. First, 100 mg (1 mg ml^{−1}) of GO powder was dispersed in 100 ml of deionized water *via* a high-shear homogenizer (FLUKO, Germany) at 1000 rpm for 3 min. Next, the GO suspension was exfoliated *via* a Sonics ultrasonic processor (750 W, 40 kHz) with 40% amplitude for 10 min. Then, 4 ml of HBr was mixed with the GO suspension. After ultrasonic dispersion by an ultrasonic bath for 10 min, the mixture was stirred for 2 h.

2.3 Precleaning of the nickel foam (NF)

Prior to these chemical processes, NF (1 cm × 3 cm) was cleaned consecutively in 6 M HCl, DI water, and ethanol with ultrasonication. Following this, the NF was dried at 60 °C for 12 h in a vacuum oven.

2.4 Preparation of the Ni/Co/Al–LTH@BG hybrid on nickel foam (NCA-L@BG–NF)

We designed a new technique for the synthesis of NCA-L@BG–NF by the *in situ* crystallization of metal nitrate using brominated graphene (BG) suspension and NF precursors followed by a single-step hydrothermal process. First, 0.005 M of Ni(NO₃)₂·6H₂O, 0.005 M CoCl₂·6H₂O, and 0.005 M Al(NO₃)₃·6H₂O were dissolved in 75 ml of deionized water and stirred for 2 h. Subsequently, 1.5 g of urea was added to the solution and the entire solution was stirred vigorously with a magnetic stirrer for another 0.5 h. Then, 20 ml of the as-prepared BG suspension was mixed into the LTH mixture *via* stirring for another 0.5 h. The entire solution was then transferred to a 100 ml Teflon-lined autoclave and a piece of cleaned Ni foam was dipped into the solution. The autoclave was heated to 150 °C for 12 h. After the reaction was complete, the autoclave was cooled to room temperature. Finally, the Ni foam was washed successively with DI water and ethanol and dried at 60 °C for 12 h in a vacuum oven. Three different compositions of LTH were prepared by keeping Ni(NO₃)₂ constant and varying the Al(NO₃)₃:CoCl₂ mole ratios for the initial feeding, such as 1 : 1 : 1, 1 : 2 : 2, and 1 : 3 : 3; the final composites were labeled as NCA-L@BG–NF-1, NCA-L@BG–NF-2, and NCA-L@BG–NF-3, respectively. The weights of the deposited materials were determined gravimetrically by measuring the change in weight of the nickel foam before and after the material deposition. The mass of the active material on the NF was about 1.5 mg. For comparison, NCA-L–NF and NCA-L@G–NF were fabricated in the absence of BG

with the same experimental conditions on nickel foam as binder-free electrodes.

2.5 Characterization

The surface morphology, structure, and composition of the samples were investigated by scanning electron microscopy (SEM) (JEOL JSM6480A microscope), transmission electron microscopy (TEM, JEM-2100F), and by high-resolution transmission electron microscopy (HRTEM, JEOL 2010). The crystallographic structures of the samples were determined by X-ray diffraction (XRD) (Rigaku TTR-III) equipped with Cu K α radiation ($\lambda = 0.15406$ nm). Fourier transform infrared spectra (FT-IR) of the samples were recorded in the range 4000–500 cm^{-1} with 2 cm^{-1} resolution using the KBr pellet technique on a Nexus FT-IR spectrophotometer (Thermo Nicolet, USA). Raman spectra were collected using an INVIA spectrophotometer (Renishaw, UK). X-ray photoelectron spectroscopy (XPS) measurements were done on a KRATOA XSAM800 XPS system with Mg K α source.

2.6 Electrical and electrochemical performances

All the electrochemical measurements of the NCA-L-NF, NCA-L@G-NF and NCA-L@BG-NF, deprived of any additive/binder, with three different mole ratios were carried out on a CHI 660E (Chenhua, Shanghai, China) electrochemical workstation using a common three-electrode cell. The electrochemical measurements were made in 6 M KOH electrolyte at room temperature. Herein, all the prepared samples were used as working electrodes, while a platinum foil and a saturated calomel electrode (SCE) were used as the counter and reference electrodes, respectively. Their proposed applications could be implemented with much discretion using cyclic voltammetry (CV). The voltammetric measurements were carried out within a potential range of 0 to 0.6 V (vs. SCE) at different scan rates of 5, 10, 20, 40 and 50 mV s^{-1} , respectively. The cycle life was tested on a LAND CT2001A test system through a galvanostatic charge–discharge technique, and the cycling performances of the obtained electrode materials were explored. GCD curves were measured at different current densities 6, 8, 10, 15 and 20 A g^{-1} , respectively in the potential range of 0–0.55 V (vs. SCE). Cycle stability measurements were tested at 20 A g^{-1} for 2000 cycles. Electrochemical impedance measurement (EIS) data were collected in the frequency range from 100 kHz to 0.01 Hz at an open circuit potential with an AC voltage amplitude of 5 mV. The specific capacity (C g^{-1}) of the prepared sample-electrodes based on the galvanostatic discharge curve was computed using the following equation:²²

$$Q = I\Delta t/m \quad (i)$$

where I (mA) is the discharge current, m (mg) is the mass of the active materials in the electrode, and Δt (s) is the discharge time.

3. Results and discussion

3.1 Structural characterization of electrode material

The choice of material and its synthesis is extremely important when fabricating high-performance electrode materials. In view of the importance of LDHs, we prepared a fascinating combination of Ni, Co, and Al layered triple hydroxides (LTHs) by directly growing on nickel foam hybridized with a BG-functionalized graphene layer as a promising electrode material. To account for the formation of NCA-L@BG-NF and the robust adhesion on nickel foam, we present the schematic of the growth mechanism in Fig. 1. To describe the possible formation mechanism of the NCA-L@BG-NF, we referred to the Ostwald ripening and self-assembling mechanism, which involves the nucleation and growth of NCA-L crystals; at the same time under the same temperature, the LTH was hydrothermally hybridized with BG on nickel foam.²³ Initially as shown in the schematic in Fig. 1, Ni, Co, and Al metal salts in water were magnetically stirred to enable their dispersion; simultaneously, GO and HBr were also magnetically stirred together in order to obtain the functionalized BG (step I). This leads to an *in situ* release of OH^- and CO_3^{2-} at a controlled rate from urea decomposition, which further initiates the precipitation of Ni^{2+} , Co^{2+} , and Al^{3+} (ref. 24) (step II). Simultaneously, Ni^{2+} , Al^{3+} , and Co^{2+} from $\text{Ni}(\text{NO}_3)_2$, CoCl_2 , and $\text{Al}(\text{NO}_3)_3$ get mixed with NH_3 , which leads to the formation of an amine complex. The high specific surface area of BG makes it easy to adsorb a large number of amine complexes of Ni^{2+} , Co^{2+} , and Al^{3+} . Such amine complex metal ions easily get adsorbed on the heterogeneous surface of the substrate (NF) hydrothermally, or by electrostatic, or van der Waals forces (step III). Initially, the solution was neutral but with time and increasing temperature, the solution becomes alkaline. At this condition, the $\text{Ni}(\text{NH}_3)_4^{2+}$, $\text{Co}(\text{NH}_3)_4^{2+}$, and $\text{Al}(\text{NH}_3)_6^{3+}$ are unstable and the following reactions occur to form mixed metal hydroxides. Then, nucleation and growth occurs through an aggregation-based mechanism, to produce crystals with hierarchical architectures that contribute to the final structure of the electrode.²⁵

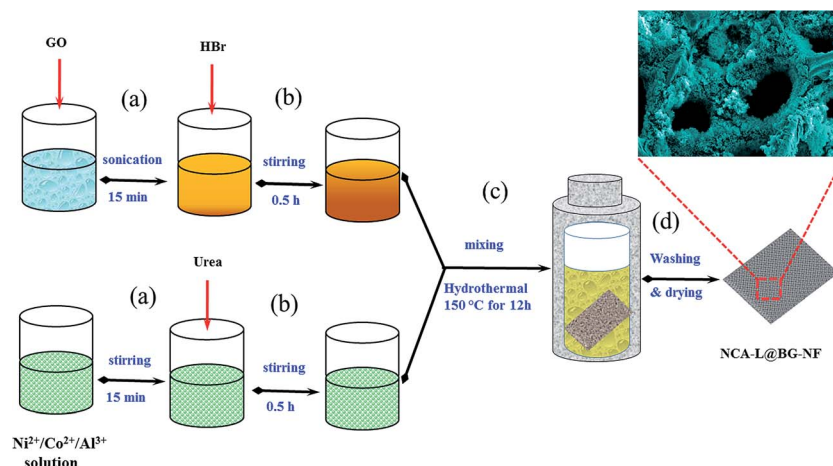

Fig. 1 Schematic representation of the formation mechanism of NCA-L@BG-NF.

3.2 Morphology and structural characterization

The hierarchical configuration of the NCA-L-powder, NCA-L-NF, NCA-L@BG-NF-3 sample electrodes were investigated by scanning electron microscopy (SEM) and transmission electron microscopy (TEM) at different magnifications as shown in Fig. 2. In a few studies reported in the literature, the SEM images of LTH samples, usually prepared by predictable methods, exhibit hexagonal-plate and flower-like

morphologies.²⁶ In case of this study, we observe that the 3D hierarchical NCA-L-powder has identical thin hexagonal flacks arranged in a flower-like morphology, during the hydrothermal process Fig. 2a and b.⁷ Fig. S1† shows an SEM image of the bare NF, which has an even surface providing a high specific surface area (110PPI), with a microporous structure that enables sufficient loading of LTH materials per unit area.^{27,28} Fig. 2c and d present the decoration of NCA-L on NF with a flower-like morphology. Fig. 2e and f show that the surface of the NF was

Fig. 2 SEM analysis: (a, b) low and high resolution SEM images of NCA-L powder showing a rose-like morphology, (c, d) NCA-L-NF, and (e, f) NCA-L@BG-NF-3, respectively.

covered completely with hexagonal flakes of NCA-L@BG, where the NF was decorated with a large number of LTH hybridized with BG flakes both outside and inside, and the porous structure of NF was retained even after the hydrothermal growth. This hierarchical array could be expected to improve the capacitive performance of the electrode by enabling an easy access of ions and high ionic mobility without any blocks from binders at the electrode/electrolyte interface.²⁹ TEM analysis was performed to further examine the detailed morphology of the NCA-L powder and the NCA-L@BG-NF-3. From Fig. 3a and b, one can observe the thin hexagonal nanoflakes with diameters from 39.5 to 69.5 nm and lengths from 83 to 141 nm in NCA-L powder. The hexagonal nanoflakes are very indistinct, but can be seen as an homogeneous contrast, reflecting their thin nature and uniform thickness.³⁰ Fig. 3c and d, related to NCA-L@BG-NF-3, show BG sheets distributed on the surface of hexagonal NCA-L flakes. The face-to-face assembly of BG and NCA-L improves their contact area, which is beneficial for efficient electron transport between the active material and NF. It was also observed that the NCA-L flakes were intimately interacting with the functionalized graphene sheets and most of them were parallel to the graphene sheets.³¹ Both the BG sheets and NCA-L flakes could be clearly observed in NCA-L@BG-NF-3, which showed a significantly different assembly of NCA-L sheets from hexagonal structures to graphene-supported LTH sheets as reported earlier. This is attributed to the anchoring effect of the polar surfaces of the BG sheets on the NCA-L sheets due to the electrostatic interactions between them.³² Moreover, the high-resolution TEM (HRTEM) image (Fig. 3e) of the NCA-

L@BG-NF-3 hybrid further confirms that the structure is crystalline, with alternating clear lattice fringes contributing to the thickness of 0.75 nm,³³ which corresponds to the d_{003} value of rhombohedral NCA-LTH in accordance with the XRD results.³⁴ Furthermore, the selected area of NCA-L@BG-NF-3 used for the SEM EDS elemental mapping confirmed the uniform distribution of Ni, Co, Al, Br, and C (Fig. 4a). Fig. 4b depicts the EDS spectrum analysis, where the atomic percentage of the individual components were calculated and the results confirmed the presence of Ni, Co, Al, Br, and C in NCA-L@BG-NF-3.³⁵

X-ray diffraction (XRD) analysis provides information on the crystallinity of materials. Fig. 5a illustrates the XRD patterns of the NCA-L@BG-3 powder, NCA-L@BG-NF-3, NCA-L@G-NF, and NCA-L-NF samples. The diffraction patterns of all samples correspond well with the standard compound $\text{Co}_6\text{Al}_2\text{CO}_3(\text{OH}) \cdot 16\text{H}_2\text{O}$ (JCPDS: 51-0045), with the well-defined diffraction peaks indexed to a series of (003), (006), (012), (015), (018), (110), and (113) planes.³⁶ Moreover, some of the diffraction peaks could also be indexed to a distinctive rhombohedral phase Ni-Al hydrotalcite (JCPDS No. 15-0087).³⁰ The sharp diffraction peaks of powder scratched from NCA-L@BG-NF-3 revealed that the crystal grew along a certain axis with high crystallinity and an excellent layered feature with an interlayer distance of 0.75 nm (d_{003}), indicating the occupancy of CO_3^{2-} ions and water molecules in the interlayer spaces.³⁴ No typical diffraction peaks of BG or graphene were observed in NCA-L@BG-3 powder, NCA-L@BG-NF-3, or NCA-L@G-NF hybrid, indicating that the integration of BG nanosheets does not significantly affect the crystal structure of NCA-LTH.³⁷ In addition, the functionalized

Fig. 4 (a) SEM EDS mappings (Ni, Co, Al, C, and Br) and (b) EDS spectrum for NCA-L@BG-NF-3; (c) Raman spectra of GO, NCA-L-NF, NCA-L@G-NF, and NCA-L@BG-NF-3.

graphene layers are highly discrete in the hydrotalcite structure, and a small amount of C inserted into the LTHs does not hamper the growth of LTH crystals.³⁸ Moreover, the weak peaks of the rest of the samples grown on NF at 11.6, 23.3, and 34.2 were complimented with the peaks of the NCA-L@BG-3 powder, demonstrating that the samples were successfully grown on Ni foam. In addition, three strong peaks (denoted by “♣” in Fig. 5a) located at 44.5°, 52.1°, and 76.42° for all samples were indexed to metal Ni (PCPDF 04-0850) from the NF substrate.³⁹

The surface chemical composition of the samples scratched from the NCA@G-L-NF, NCA-L@BG-NF-1, NCA-L@BG-NF-2, and NCA-L@BG-NF-3 samples were analyzed by FT-IR spectroscopy, with the spectra shown in Fig. 3f. The spectra of all samples exhibit a broad absorption band at around 3466 and 3434 cm^{-1} , originating from the stretching vibration of OH^- groups of the metal hydroxide layer and interlayer water, and from hydrogen bonding among the hydroxyl groups in all the LTH samples. The weak band at 1625 cm^{-1} is due to the bending mode of water molecules.⁴⁰ The characteristic peaks at 1369 and 781 cm^{-1} are attributed to the ν_3 vibration and bending modes of the interlayer anion (CO_3^{2-}), respectively, which was released from urea hydrolysis during the hydrothermal procedure.^{41,42} The above analysis demonstrated that the water molecules and carbonate ions had been successfully intercalated into the interlayer space of NCA-L during the assembly process. For all the LTH samples, the bands recorded below 800 cm^{-1} could be accounted for from the lattice vibration modes for M–O (Ni, Co, Al–O).⁹ In comparison with GO (S2), most of the peak intensities corresponding to carbonyl, epoxide, and ether groups have disappeared or weakened in the FT-IR spectrum of NCA-L@G-NF and NCA-L@BG-NF-3,

signifying that NCA-L was successfully combined with GO or BG in the as-prepared hybrid electrode.⁴³

Raman spectroscopy is a non-destructive technique, which is widely used to characterize the graphitization of materials. The Raman scattering spectra of the GO, NCA-L-NF, NCA-L@G-NF, and NCA-L@BG-NF-3 samples were recorded and are shown in Fig. 4c. For graphitic materials, there are usually two feature peaks known as the D band and G band. The D band (usually observed at 1300–1400 cm^{-1}) arises from a breathing mode of point photons of A_{1g} symmetry; the presence of the D band indicates defects in the graphene layer. The G band (in the region of 1500–1600 cm^{-1}) arises from the first order scattering of the E_{2g} phonon at the Brillouin zone center, resulting from the bond stretching of sp^2 carbon lattice pairs in both rings and chains.^{44,45} A strong peak located at 531 cm^{-1} is typically assigned to NCA-LTH.⁹ It is known that the integrated intensity ratio of the bands (I_D/I_G) is used to qualitatively analyze the structural defects and disorder of graphite materials. Thus, it was found that GO has an I_D/I_G ratio of 0.93 and then, its values gradually increase from NCA-L@G-NF (1.04) to NCA-L@BG-NF-3 (1.06). This is related to the defect density within the graphene structure and to the concentration of sp^3 hybridized carbon atoms, which evidently indicates the intimate contact of LTH with BG and graphene species, suggesting the increased structural defects in all the prepared samples.⁴⁶ Comparative studies of the Raman spectra (Fig. 4c) show that the G band of NCA-L@BG-NF-3 shifts to lower frequency (compared with that of GO). This deviation ($\sim 19 \text{ cm}^{-1}$) in the G band can be attributed to recovery of the conjugated structure of the carbon atoms, which resonate at lower frequencies. In addition, these shifts in the Raman peaks could be attributed to the formation of

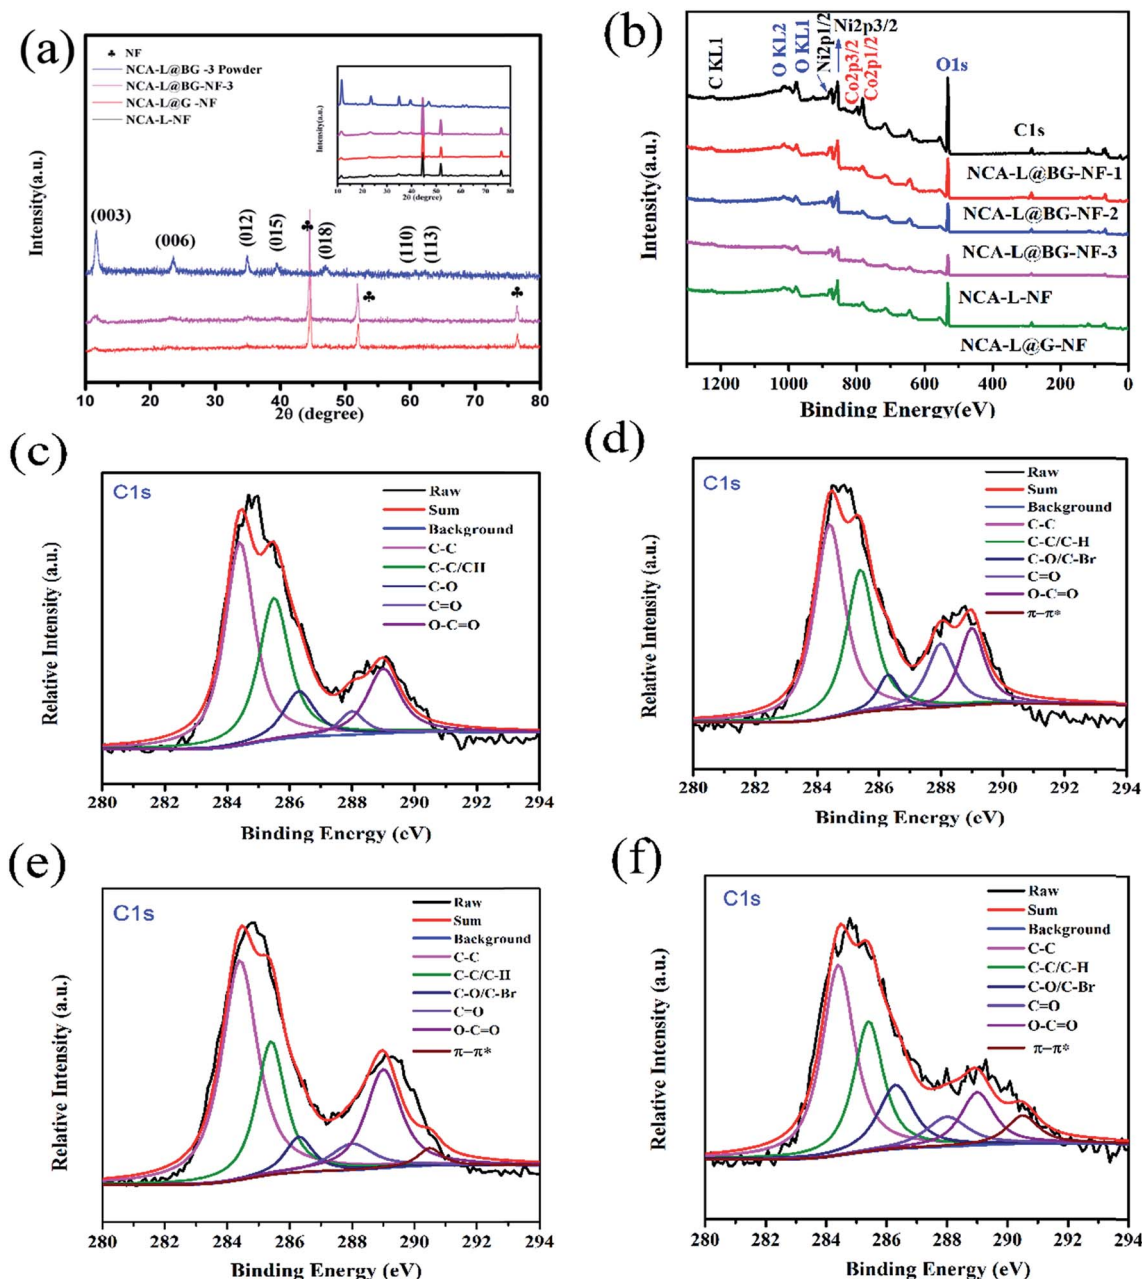

Fig. 5 (a) XRD patterns of NCA-L@BG-3 powder, NCA-L@BG-NF-3, NCA-L@G-NF, NCA-L-NF; (b) XPS survey spectra of the samples (c); C 1s XPS spectra of NCA-L@G-NF (d), NCA-L@BG-NF-1 (e), NCA-L@BG-NF-2; and (f) NCA-L@BG-NF-3.

abundant sp^3 C-H bonds. The dense ripples also contribute in confirming the bromination of graphene in the NCA-L@BG-NF-3 sample.¹³

XPS analysis was used to determine the accurate composition, chemical bonds, and oxidation states of the elements in the NCA-L-NF, NCA-L@GN-NF, and NCA-L@BGN-NF with three different feeding mole ratios. As shown in Fig. 5b–f, the survey spectra of all the prepared samples present characteristic peaks of C 1s, O 1s, Ni 2p, Co 2p, and Al 2p, confirming the presence of C, O, Ni, Co, and Al. Furthermore, Br 3d peaks were also observed in the spectra of the NCA-L@BG-NF with three different feeding mole ratios, proving that the bromination

along with LTH formation had successfully proceeded during the hydrothermal process. In Fig. 5b–f, the high-resolution C 1s spectra of the samples were fitted and divided into six peaks, corresponding to different oxygen-containing functional groups that are referred here as six types of carbon bonds: C-C (284.8 eV), C-C/C-H (285.28 eV), C-O/C-Br (286.88 eV), C=O (288.78 eV), O-C=O (289.0 eV), and $\pi-\pi^*$ interaction (290.5 eV).^{47,48} The effect of bromination on the electronic structure of graphene was checked by comparing the XPS C 1s spectra of the NCA-L@G-NF with all the brominated samples as shown in Fig. 3c–e. Furthermore, the presence of the $\pi \rightarrow \pi^*$ shake-up, which is characteristic in materials such as graphene with delocalized p-

electron systems, causes further overcrowding in the C (1s) region. The decline of a feature around 291 eV, corresponding to the $\pi \rightarrow \pi^*$ shake-up transition, can be attributed to partial disruption of the π electrons or bromination of the system.^{49,50} Furthermore, the C–O and C–Br bonds have very similar binding energies, whereby C–O has been reported to be located at 286.6 eV and C–Br at 286.2 eV.¹⁴ A detailed high-resolution peak fitting analysis of the Ni, Co, Al, and Br spectra for all the prepared samples are shown in Fig. S3.† The quantitative elemental composition of the samples obtained from the XPS analysis can be seen in Table S1.† The relative atomic amounts of C increased in the order of NCA-L@G-NF < NCA-L@BG-NF-1 < NCA-L@BG-NF-2 < NCA-L@BG-NF-3. While the relative atomic amounts of O decreased in the order of NCA-L@G-NF > NCA-L@BG-NF-1 > NCA-L@BG-NF-2 > NCA-L@BG-NF-3. This may be due to the reason that part of the oxygen-containing functional groups on the GO surface were removed or had bonded with Br atoms in the hydrothermal reaction, leading to the reduction of active sites for the adsorption of bivalent and trivalent cations.

3.3 Electrochemical performance

The electrochemical behavior of the highly open framework of the as-synthesized hybrid electrodes NCA-L@NF, NCA-L@G-NF, and NCA-L@BG-NF with three different feeding mole ratios were investigated by cyclic voltammetry (CV), galvanostatic charge–discharge, and electrochemical impedance (EIS) measurements in 6 M KOH aqueous electrolyte. Fig. 6 (a) shows the CV curves of NCA-L@NF, NCA-L@G-NF, and NCA-L@BG-NF with three different feeding mole ratios recorded at scan rates of 5 mV s^{−1}. A couple of anodic/cathodic redox peaks can be seen in the CV curves of each sample, indicating that the faradic redox reaction related to Ni²⁺/Ni³⁺ and Co²⁺/Co³⁺ with the aid of OH[−] are involved during the charge–discharge process contributing to the pseudocapacitance.¹¹ The redox reaction can be represented as follows:

In addition, the asymmetrical behavior in the cathodic peaks of the NCA-L@NF, NCA-L@G-NF, NCA-L@BG-NF-1, NCA-L@BG-NF-2, and NCA-L-NF-3 samples show kinetic irreversibility in the faradaic process. This might be assigned to resistance polarization in the region of ion diffusion in the porous electrode during the redox reactions.^{15,52} Furthermore, the integral area of the CV curves are significantly increased in the order of NCA-L@BG-NF-3 > NCA-L@BG-NF-1 > NCA-L-NF > NCA-L@BG-NF-2 > NCA-L@G-NF, suggesting that the NCA-L@BG-NF-3 has a much higher average specific capacitance. In Fig. 6b, the galvanostatic charge/discharge measurements of the as-prepared electrodes in the potential range of 0–0.5 at a very high current density of 6 A g^{−1} are illustrated. As can be seen from the curves of all the prepared hybrids, the charge/discharge curves were non-linear, which further confirms that

the redox reaction occurs during the process.^{18,53} The longest discharge time of NCA-L@BG-NF-3 suggested that this composite electrode had the best charge-storage performance. At a current density of 6 A g^{−1}, the specific capacities were calculated to be 1998 C g^{−1} for NCA-L@BG-NF-3, 1992 C g^{−1} for NCA-L@BG-NF-1, 1890 C g^{−1} for NCA-L-NF, 1770 C g^{−1} for NCA-L@BG-NF-2, and 1554 C g^{−1} for NCA-L@G-NF as illustrated in Fig. 6c. The results suggest that the NCA-L@BG-NF-3 electrode exhibited superior specific capacity in the highly concentrated 6 M KOH, indicating its enhanced charge-storage performance.^{54,55} In addition, with increase in concentration, the ionic conductivity of the electrolyte increased, which not only facilitated a high charge transfer, but also decreased the diffusion resistance, resulting in enhanced electrochemical performance.⁵⁶ This could be attributed to the synergetic effect between conductive BG and NCA-L-NF when compared with pure NCA-L-NF.⁹ Because of the presence of numerous nano-channels, the graphene and BG in the electrode convey a conductive network for electron transportation. Also the unique morphology of NCA-L@BG-NF-3 acts as a perfect reservoir to facilitate enhanced contact and diffusion as well as the penetration of OH[−] ions for the highest redox processes for charge storage.⁵⁷ The CV curves of the NCA-L@BG-NF-3 electrode at various scan rates of 6, 10, 20, 40, and 50 mV s^{−1} are shown in Fig. 6d, where it can be seen that with the increase in scan rate, the anodic peak is shifted toward lower and higher potential due to polarization.⁵⁸ Each curve at the different scan rates represented redox couples, which shows that continuous faradic redox reactions of NCA-L are involved during the charge and discharge processes contributing to the total capacitance.⁵⁹ Furthermore, even at a high scan rate of 50 mV s^{−1} the shape of the redox peaks was not influenced considerably, signifying enhanced mass transportation of ions and an excellent rate capability of the electrode.⁶⁰ The same result could also be obtained from the nonlinear charge–discharge curves as shown in Fig. 6e. Fig. 6f shows the specific capacitances of NCA-L-NF, NCA@G-L-NF, NCA-L@BG-NF-1, NCA-L@BG-NF-2, and NCA-L@BG-NF-3 at various current densities of 6, 8, 10, 15, and 20 A g^{−1}. Here, NCA-L@BG-NF-3 revealed a clearly stable and higher specific capacity than that of NCA-L-NF, NCA@G-L-NF, NCA-L@BG-NF-1, and NCA-L@BG-NF-2 at all current densities. The specific capacities of NCA-L@BG-NF-3 was 1998, 1960, 1910, 1920, and 1600 C g^{−1} at 6, 8, 10, 15, and 20 A g^{−1}, respectively, with a retention rate of 80.0%, while those of NCA-L-NF at 6, 8, 10, 15, and 20 A g^{−1} was 1554, 1496, 1470, 1335, and 1220 C g^{−1}, respectively, with a retention rate of 78.5%. Thus, the rate capability of NCA-L@BG-NF-3 was remarkably enhanced compared with NCA-L-NF. The noteworthy increase in their electrochemical activity is due to the bromination of GO, which leads to the reduction. It is well-known that the use of BG is exceptionally strategic to serve as a good electronic conductor for the redox reactions to promote pseudocapacitance. Thus, the differences in the specific capacities of the NCA-L@BG-NF hybrids may originate from the hybridization of the brominated carbon alignment and bromine content in the electrodes.⁶¹

Fig. 6 (a) CV curves of NCA-L-NF and the composites at a scan rate of 5 mV s^{-1} ; (b) galvanostatic charge-discharge curves at a current density of 6 A g^{-1} respectively; (c) histogram of the specific capacity of the samples at 6 A g^{-1} ; (d) CV curves of NCA-L@BG-NF-3 at various scan rates of 5, 10, 20, 40, and 50 mV s^{-1} ; (e) galvanostatic charge-discharge curves of NCA-L@BG-NF-3 at current densities of 6, 8, 10, 15, and 20 A g^{-1} ; (f) specific capacity of the samples at current densities of 6, 8, 10, 15, and 20 A g^{-1} .

The transport characteristics of the charge carriers within the hybrid electrodes were probed by electrochemical impedance spectroscopy. Fig. 7 outlines the Nyquist plots of the sample electrodes, presenting an incomplete depressed semi-circle in the high-frequency range and a non-straight line in the low-frequency region. This phenomenon could be ascribed to the result of the frequency dependence of ion diffusion to the electrode interface.⁶² The charge-transfer resistance (R_{CT}) was calculated to be 0.366Ω for NCA-L@BG-NF-1, 0.952Ω for NCA-L@BG-NF-2, 0.108Ω for NCA-L@BG-NF-3, and 0.468Ω for NCA-L-NF, and 1.303Ω for NCA-L@G-NF, which suggests that R_{CT} decreased in the order of NCA-L@BG-NF-3 > NCA-L@BG-NF-1 >

NCA-L-NF > NCA-L@BG-NF-2 > NCA-L@G-NF. The results obtained demonstrate that NCA-L@BG-NF-3 had the lowest R_{CT} , the highest capacitive performance, the lowest diffusive resistance of ions, and the fastest electron transport at the electrode/electrolyte interface. The overall IES findings suggested that NCA-L@BG-NF-3 possessed evidently enhanced electrochemical properties, suggesting its potential to be used as an electrode for supercapacitors.^{62,63}

For supercapacitor applications, apart from the high specific capacity, the long-term cycling stability of the electrodes is also an important requirement. Fig. 8 illustrates the cycling performance of the fabricated NCA-L@BG-NF-3. On the contrary, the

Fig. 7 Nyquist plots of the EIS data for the sample electrodes.

Fig. 8 Specific capacity and coulombic efficiency (η) of (a) NCA-L@BG-NF-3, hybrid electrode as a function of cycle number (inset shows the last few charge-discharge cycles).

NCA-L@G-NF and NCA-L-NF electrodes were evaluated over 2000 galvanostatic charge-discharge cycles at a very high current density of 40 A g^{-1} and the results obtained are shown in Fig. S4.† After 2000 cycles, the NCA-L@BG-NF-3, NCA-L@G-NF, and NCA-L-NF samples retained 90.1%, 85.7%, and 64.7%, of their initial specific capacities, respectively. Thus, NCA-L@BG-NF-3 exhibited clearly the best capacitance retention compared to the other two hybrid electrodes, which might be attributed to the high efficiency electron and electrolyte transportation of BG.⁶⁴

4. Conclusion

From the outcome of our investigations, it is possible to conclude that a triple hydroxide hybrid based on Ni/Co/Al and BG was grown directly on Ni foam through a facile one-step *in situ*

crystallization hydrothermal method, achieving superior electrochemical properties as a supercapacitor electrode. Because of the well-defined hierarchical morphology, high active surface area, and synergistic contributions of the individual components, the NCA-L@BG-NF-3 hybrid demonstrated excellent electrochemical performances as an electrode material, exhibiting a maximum specific capacity of 1998 C g^{-1} at 6 A g^{-1} , excellent rate capability of 75.3% at 20 A g^{-1} , and excellent cyclic stability of $\sim 91\%$ capacitance retention after 2000 cycles at 20 A g^{-1} , with 100% coulombic efficiency, which were significantly higher than those previously reported for LDH composites. In addition, the material demonstrated good long-term cyclic stability and a low R_{CT} . Furthermore, the NCA-L@BG directly grown on the Ni foam had greatly improved electrochemical capabilities. These results suggest that the as-prepared NCA-L@BG-NF-3 hybrid could be a superior candidate for the fabrication of binder-free electrodes. It is also suggested that the proposed synthetic strategy can be extended to the fabrication of other triple hydroxide binder-free electrodes for supercapacitor applications.
