Formation of environmentally-persistent free radicals (EPFR) on \(\alpha\)-Al\(_2\)O\(_3\) clusters

Niveen W. Assaf, Mohammednoor Altarawneh, Marian W. Radny, Jomana Al-Nu’airat and Bogdan Z. Dlugogorski

Alumina oxides assume prominent catalytic applications in a wide range of industrial processes. However, alumina surfaces also serve as potent promoters in the heterogeneous formation of the notorious environmentally-persistent free radicals (EPFR). Herein, we theoretically examine dissociative adsorption mechanisms of phenol molecules over Al\(_2\)O\(_3\) and hydrated Al\(_2\)O\(_3\)-\(n\)H\(_2\)O clusters that mimic dehydrated and hydrated alumina structures, respectively. We show that fission of the phenol's hydroxyl bond over dehydrated alumina systematically incurs lower energy barriers in reference to the hydrated structures. A 1,2-water elimination step marks the most feasible channel in the interaction of phenol with hydrated clusters. The relevance of the acidity sites to the catalytic activity of alumina is clearly supported by the finding that the catalytic activity of the alumina surface in producing the phenoxy/phenolate species reversibly correlates with the degree of hydroxyl coverage. Desorption of adsorbed phenolates requires sizable desorption energies, and thus is expected to facilitate surface-mediated condensation into dioxin-like moieties.

1. Introduction

Alumina oxide represents one of the most important catalytic and catalyst-support materials,\(^{1,3}\) for chemical reactions. It also finds direct applications in dielectric materials, substrates for electronics, packing materials and radiation dosimeters.\(^{4,5}\) Over the last two decades, the surface chemistry of alumina oxides has been a distinct research topic in catalysis chemistry. Most of these studies have focused on the surface/water interface conditions, where the chemistry of the surface is greatly affected and accordingly alters its reactivity and catalytic performance.\(^{6-8}\)

The interaction of alumina surfaces with water molecules\(^{9,10-14}\) results in water- and hydroxyl-covered surfaces, in which the degree of coverage is highly sensitive to temperature.\(^{15}\) Heating and cooling processes can reversibly either add or remove hydroxyl groups from the surfaces, as confirmed experimentally by IR and NMR measurements.\(^{16,17}\) For instance, X-ray diffraction data by Dyer et al.\(^{18}\) revealed the formation of Al(OH)\(_3\) on the \(\gamma\)-Al\(_2\)O\(_3\) surface, which disappeared after heating to 473.15 K. This has also been confirmed by Raman and infrared spectroscopy where several sharp peaks in the region around 3600 cm\(^{-1}\) have been observed after hydration of the \(\gamma\)-Al\(_2\)O\(_3\) powder. X-ray photoemission experiments by Liu et al.\(^{19}\) pointed out to water dissociation; most likely at surface defect sites.

It has become evident that,\(^{15,16,20,21}\) the differences of the coordination of Al atoms of the alumina surface lead to form different terminal hydroxyl termination or interactive phases. An experimental study by Pimentel and McClellan\(^{22}\) revealed that, surfaces encompasses two main categories of surface hydroxyl groups; isolated hydroxyl groups with a sharp infrared bands (>3600 cm\(^{-1}\)), and self-associated hydroxyl groups with a broad, intense band (<3600 cm\(^{-1}\)). Apart from this, self-associated hydroxyl groups differ from the isolated groups in the presence of the hydrogen bond connection between adjacent moieties. Detailed examination of chemical sites on Al\(_2\)O\(_3\) surface\(^{23,24}\) confirmed the findings of Pimentel and McClellan.\(^{22}\) Overall, five different classes of isolated hydroxyl groups have been detected by IR spectroscopy,\(^{23,24}\) Knözinger et al.\(^{1}\) attribute the difference in vibrational frequencies among these classes to the coordination number of alumina \((i.e.;\) either tetrahedral and/or octahedral coordination).

The chemical makeup \((i.e.;\) adsorption and decomposition\()\) of the hydroxyl groups over alumina surface constitutes a key factor in clarifying the reactive/catalytic nature of alumina. As stated earlier, heating can reversibly remove the hydroxyl groups from the alumina surface,\(^{16,17,25}\) leading to the formation of Lewis acid–base pair sites, and thus increases the catalytic activity of the surface. Along a similar line of enquiry, Ballinger and Yates\(^{26}\) have performed a detailed investigation into the correlation between Al-OH group removal and the number of Lewis acid sites \(via\) CO molecular adsorption. The authors have found that, heating leads to the decomposition of the associated hydroxyl groups, leaving only isolated hydroxyl groups on
the surface at a temperature range of 475–800 K. This has been viewed as the driving force of the catalytic activity of alumina, either via hydrogen bonding to the hydroxyl group and/or via lone pair donation to Lewis acid sites. A study by Hendriksen et al.\textsuperscript{37} measure the heat of adsorption of water on both \(\alpha\)- and \(\gamma\)-alumina powders via immersion calorimetry. It has been indicated that, the heat of adsorption on both termination depends primarily on the degree of hydration prior to water adsorption.

Over a wide range of operational pressure and temperatures, alumina exhibits a variety of crystallographic structures such as \(\alpha\) phase or corundum, which is the most thermodynamically stable phase,\textsuperscript{28} and other alumina phases such as \(\delta\), \(\beta\), \(\kappa\), \(\eta\), \(\theta\) and \(\chi\).\textsuperscript{29,30} Literature density function theory (DFT) investigations have considered water adsorption and dissociation over \(\alpha\)-Al\(_2\)O\(_3\) surfaces from the dry to the fully hydroxylated surfaces. A detailed analysis and discussion on the subject was presented by Wang et al.\textsuperscript{17} The authors have found that, a fully hydrated alumina \(\alpha\)-Al\(_2\)O\(_3\) (0001) surface, when the surface Al atom is triply hydroxylated, exhibits relatively inertness toward further hydroxylation. In an insightful analysis into the interaction of water molecules and a \(\alpha\)-Al\(_2\)O\(_3\) (0001) surface, Wirth and Saalfrank\textsuperscript{32} found that 1,2-dissociation pathway is the most kinetically feasible mechanism, where Al surface atoms are hydroxylated and the nearby oxygen atoms are protonated.

Recent theoretical investigations addressed the interaction of hydrated and dehydrated \(\alpha\)-Al\(_2\)O\(_3\) surfaces towards different molecules.\textsuperscript{33–35} Shukla and Hill\textsuperscript{33} have performed a detailed investigation of the molecular interaction of 2,4,6-trinitrotoluene (TNT) molecule with the \(\alpha\)-Al\(_2\)O\(_3\) (0001) surface demonstrating that TNT acquires strong covalent interaction in a parallel orientation with the surface. The same group\textsuperscript{34} found that molecular adsorption of TNT over hydroxylated alumina surface is much weaker when compared to the dehydrated surface. Similarly, Rohmann et al.\textsuperscript{35} investigated molecular interaction of carbon monoxide with hydroxylated alumina surface, reporting that molecular CO exhibits strong interaction with a 25% degree of hydroxylated surface and this interaction is significantly stronger when compared with that over the clean dehydrated alumina. In a follow-up study on \(\text{H}_2\text{S}\) removal via \(\gamma\)-Al\(_2\)O\(_3\) surfaces with different hydroxyl coverage, Ren et al.\textsuperscript{36} revealed that, the bonding strength of \(\text{H}_2\text{S}\) on hydrated alumina surface is lower than that over a dehydrated termination. For example, calculated binding energy for 8.9 OH per nm\(^2\) hydroxyl coverage for \(\gamma\)-Al\(_2\)O\(_3\) (110) amounts to −68 kJ mol\(^{-1}\) whereas the corresponding value of the dehydrated surface stands at −114 kJ mol\(^{-1}\). XPS studies by Kelber et al.\textsuperscript{37} investigated the interaction between Cu and the hydrated \(\alpha\)-Al\(_2\)O\(_3\) (0001) surface to report an enhanced interaction of copper to the surface of alumina owing to the presence of a surface hydrated layer. There is a rather limited literature account on reactions of hydrocarbons on alumina clusters. Most of relevant studies have considered extended surfaces of alumina.\textsuperscript{34,35,38} Nonetheless, it has been shown that alumina clusters encompass effective catalytic active sites present on surfaces; i.e., the surface Al–O bonds.\textsuperscript{39,40} Therefore, alumina clusters in many theoretical studies (i.e. (Al\(_2\)O\(_3\))\(_n\)) are being applied as representative models for both \(\alpha\)-Al\(_2\)O\(_3\) and \(\gamma\)-Al\(_2\)O\(_3\) surfaces. Alumina clusters imitate both the experimental measurements and DFT surface properties. Additionally, clusters\textsuperscript{41,42} were shown to illustrate an effective stability against relaxation often encountered in extended alumina surfaces.

Phenol molecule is among the most commonly discussed precursors for the synthesis of poly chlorinated dibenzo-p-dioxins and dibenzo furans (PCDD/Fs).\textsuperscript{43–45} Heterogeneous formation of PCDD/Fs via surface-mediated coupling of chlorinated phenols were investigated on many oxide systems, including Al\(_2\)O\(_3\),\textsuperscript{46–47} Co\(_3\)O\(_4\),\textsuperscript{48} CuO,\textsuperscript{49,50} TiO\(_2\) (ref. 47) and Fe\(_2\)O\(_3\).\textsuperscript{51} In our recent study,\textsuperscript{27} we theoretically investigate the interaction of phenol molecule with the dehydrated \(\alpha\)-Al\(_2\)O\(_3\) (0001) surface. We have found that, alumina surface is catalytically very active in producing phenolate (i.e., surface-bound phenoxo) with a modest activation energy of 43 kJ mol\(^{-1}\), thus, signifying as an accessible route for the formation of persistent surface-bound radicals. However, when considering the temperature range of the cooling-down zone of the combustor (i.e.; 746–1146 K), all models of alumina (i.e.; polymorphs, surfaces and/or clusters) assume different hydration coverage. Therefore, the effect of the degree of hydration, on dissociative adsorption of phenol, can play an important role in attaining a detailed understanding of the catalytic activity of the surface. Thus, it is very important to shed light into the generation of the environmentally persistent free radicals (EPFRs)\textsuperscript{29,30} on alumina surface with varying hydroxyl coverages.

In summary, the current work is part of our ongoing effort to reveal mechanistic and kinetic factors dictating the catalytic role of alumina surfaces in surface-mediated formation of phenoxy-type EPFR. The study provides a detailed investigation of the interaction of a phenol molecule with different hydration coverage of alumina clusters and therefore offers important insights into the role of the surface adsorbed water in the catalytic activity of alumina toward the generation of adsorbed phenoxy radicals. The present study expands on our recent investigation,\textsuperscript{31} in which we considered a dehydrated \(\alpha\)-Al\(_2\)O\(_3\) (0001) surface. Overall, this study has a three-fold aim; (i) to report modes of interaction of phenol with different hydration coverages of alumina clusters, (ii) to compare between the catalytic activity of hydrated and dehydrated alumina clusters toward the formation of the adsorbed phenolate via two distinct pathways; namely direct fission of the phenol O–H bond and elimination of water molecules and to (iii) to construct a simplified kinetic model for the conversion of phenol into adsorbed phenoxy radicals.

2. Methodology

Dmol\(^3\) program\textsuperscript{54,55} performs all structural optimization, energy calculations and vibrational frequencies based on the generalized gradient approximation (GGA) of the Perdew–Burke–Ernzerhof (PBE) functional.\textsuperscript{56} The computational methodology comprises Grimme dispersion correction,\textsuperscript{57} together with the basis set of double numerical plus polarization (DNP). Total energy and forces on each atom converge with tolerance to less than \(10^{-6}\) eV and \(10^{-4}\) eV Å\(^{-1}\), respectively.
We computed the binding energies ($E_b$) for the adsorption based on the energies of a phenol/Al$_2$O$_3$ system $E_{\text{cluster+phenol}}$, the clean alumina cluster $E_{\text{cluster}}$, and an isolated phenol molecule $E_{\text{phenol}}$:

$$E_b = E_{\text{cluster+phenol}} - E_{\text{cluster}} - E_{\text{phenol}}$$  \hspace{1cm} (1)

Reaction rate constants were estimated based on the conventional transition state theory (TST),\textsuperscript{58} we fit reaction rate constants to the two-parameters Arrhenius formula, $k(T) = A \exp(-E_b/(RT))$, over the temperature range of 300 K to 1000 K, according to:

$$k(T) = \frac{k_B T}{\sigma h} \exp \left( \frac{\Delta S^\ddagger}{R} \right) \exp \left( \frac{-\Delta H^\ddagger}{RT} \right)$$  \hspace{1cm} (2)

where: $k_B$ is Boltzmann’s constant, $h$ signifies Planck’s constant, $R$ is the universal gas constant. Calculated vibrational frequencies enable to calculate thermodynamic functions; i.e., entropies and enthalpies. $\Delta S^\ddagger$ and $\Delta H^\ddagger$ stand for temperature-dependent entropy and enthalpy of activation, correspondingly. $\sigma_c$ represents the reaction degeneracy number. DMol\textsuperscript{3} computes entropy values based on well-documented statistical thermodynamics equations.\textsuperscript{59} The enthalpy (at the desired temperature) has been computed relatively to the zero-point energy at 0 K.

3. Results and discussions

3.1. Water adsorption on Al$_2$O$_3$ cluster

Starting with dehydrated alumina clusters, Fig. 1 displays two water-free geometrical monomers of alumina near-cyclic Al$_2$O$_3$Al that adapt $D_{3h}$ symmetry, and a linear O=Al−O−Al=O chain structure. As illustrated in Fig. 1, the cyclic dehydrated alumina, Al$_2$O$_3$Al, contains three Al−O bonds with distances of ~1.82 Å. This structure was found to be energetically less stable\textsuperscript{60} than the linear chain structure due to the repulsion between the two cations (Al$^{3+}$). In the latter configuration, alumina adapts a linear structure with one bridging and two non-bridging oxygen atoms. Calculated bond angle and bond lengths, in both structures, are in agreement with the literature analogous values.\textsuperscript{60,61}

Moving on now to consider how the geometries of alumina cluster are compared with those in alumina surface. Fig. 2 displays top and side views of $\alpha$-Al$_2$O$_3$ (0001) surface (i.e., the thermodynamically most stable alumina surface\textsuperscript{62,63} and the $D_{3h}$ structure. As can be seen from the figure, Al−O bonds lengths in both structures are within 0.01 Å. This close agreement serves to testify that considered cyclic dehydrated structure contains similar active sites to those present in the surface.

A study by Johnson and Panas\textsuperscript{60} examine water adsorption and hydrolysis on molecular Al oxides and hydroxides solvation versus cluster formation. They found that, dehydrated alumina clusters, both cyclic and linear chain, reacts with water molecules through accessible energy barriers in the range of 33–110 kJ mol$^{-1}$. Further addition of water molecules leads to a series of Al$_2$O$_3$·$n$H$_2$O structures.

Fig. 3 illustrates mechanism of successive addition of water molecules to the dehydrated cluster of alumina (i.e.; cyclic and linear clusters). Starting with the cyclic structure of alumina, $D_{3h}$, the addition of a water molecule to the Al$_2$O$_3$ bond results in the formation of the Al$_2$O$_3$·1H$_2$O(c) cluster (c) which has been reported to be the most stable structure among the various configurations of Al$_2$O$_3$H$_2$ clusters.\textsuperscript{60} Typically, this structure assumes cis and trans configurations, with very similar thermodynamic stability.\textsuperscript{60} Thus, we have performed our subsequent calculations considering the cis planar molecule configurations with the $C_{2v}$ symmetry as it is marginally more thermodynamically stable than its trans counterpart; by 3 kJ mol$^{-1}$. Calculated Al$_2$O−O and Al$_2$−O$_w$ bond lengths amount to 1.75 Å and 1.70 Å, respectively. These values concur very well with the corresponding literature values by Johnson and Panas\textsuperscript{60} i.e., 1.75 Å and 1.69 Å, respectively.

Fig. 1 Optimised geometries for dehydrated Al$_2$O$_3$ clusters with the main geometrical parameters (in Å). Bond lengths in parentheses signify the corresponding experimental or theoretical values from the literature a,\textsuperscript{59} b.\textsuperscript{61}

Fig. 2 Geometrical comparison between Al$_2$O$_3$ cyclic cluster and the $\alpha$-Al$_2$O$_3$ (0001) surface.

Fig. 3 Illustration of successive addition of water to the dehydrated cluster of alumina (i.e.; cyclic and linear clusters). Starting with the cyclic structure of alumina, $D_{3h}$, the addition of a water molecule to the Al$_2$O$_3$ bond results in the formation of the Al$_2$O$_3$·1H$_2$O(c) cluster (c) which has been reported to be the most stable structure among the various configurations of Al$_2$O$_3$H$_2$ clusters.\textsuperscript{60} Typically, this structure assumes cis and trans configurations, with very similar thermodynamic stability.\textsuperscript{60} Thus, we have performed our subsequent calculations considering the cis planar molecule configurations with the $C_{2v}$ symmetry as it is marginally more thermodynamically stable than its trans counterpart; by 3 kJ mol$^{-1}$. Calculated Al$_2$O−O and Al$_2$−O$_w$ bond lengths amount to 1.75 Å and 1.70 Å, respectively. These values concur very well with the corresponding literature values by Johnson and Panas\textsuperscript{60} i.e., 1.75 Å and 1.69 Å, respectively.
Turning now to the linear chain structure, the addition of water can proceed either via cluster Al–O double bond site or via cleaving the central Al–O–Al bond. This results in the formation of the Al₂O₃ + H₂O cluster (d) and O=AlOH (g), respectively. Considering the double bond pathway; further addition of a water molecule produces the cluster Al₂O₃ + 3H₂O (e), with the C₂h symmetry. Energetics for the formation of the hydrated alumina structures in Fig. 3 has been reported by Johnson and Panas. The authors found that formation of (c) and (e) structures display an exothermic process with calculated enthalpies of −310 kJ mol⁻¹ and −184 kJ mol⁻¹, respectively. The formation of structure (g) is slightly endothermic with a low activation enthalpy at 33 kJ mol⁻¹.

3.2. Reaction of phenol with dehydrated alumina cluster

We studied the interaction of a phenol molecule with the two dehydrated alumina clusters (i.e.; cyclic and linear clusters in Fig. 3a and b). Two different reactions have been considered, denoted as pathway a and pathway b. These pathways involve the interaction of phenol molecule with cyclic and linear dehydrated alumina clusters, respectively. The optimized geometries for the reactants, transition states and products are presented in Fig. 4. Table 1 lists energies for physisorbed configurations and dissociative structures as well as prominent interatomic distances for all pathways.

We first consider the interaction along the cyclic alumina structure, pathway a. Fig. 4(a) shows, phenol molecule physically adsorbed on the cluster through a van der Waals interaction between Ophenol atom and Alcluster atom with a binding distance of 1.909 Å. The interaction proceeds via fission of the hydroxyl’s bond over Al–O cluster bond where phenoxy moiety attaches to Alcluster and deducted hydrogen atom binds to Ocluster atom. This has resulted in the optimised dissociation product Pₐ. Hence, the length of this bond increases by 13.4% with respect to that of the clean cyclic cluster (1.822 Å). This value concurs with results obtained in our recent study of the dissociative adsorption of phenol on the dehydrated α-Al₂O₃ (0001) surface (11.9%). In comparison, Wang et al. showed that the elongation of Al–O bond increased by 6.4% upon the dissociation of a water molecule over this Al–O bond.

The reaction is highly exothermic with an energy barrier of only 41 kJ mol⁻¹. Calculated binding energy of the reactant, Rₐ, and the product, Pₐ, are −129 kJ mol⁻¹ and −241 kJ mol⁻¹, respectively (based on eqn (1) in reference to separated reactants). These values also agree with the results obtained in our recent study. We found that, phenol molecule strongly interacts with the dehydrated α-Al₂O₃ (0001) surface via physisorbed binding energies in the range of −127 kJ mol⁻¹ to −202 kJ mol⁻¹, leading to the formation of an adsorbed phenolate with a modest activation energy of 48 kJ mol⁻¹.
Considering the second reaction, where phenol molecule interacts with the linear cluster chain of alumina (pathway b), phenol molecule physically adsorbs on the active Al–O double bond site of the cluster with a calculated binding distance of 2.26 Å. The O–H bond length of phenol molecule in \( R_b \) (Fig. 4) increases from the equilibrium 0.97 Å distance in the gas phase to 1.016 Å. The exothermic formation of the product \( P_b \) requires a trivial activation energy of 10 kJ mol\(^{-1}\) (via direct fission of the phenol’s O–H bond catalysed by the cluster’s Al–O linkage). Calculated binding energies of the reactant, \( R_b \), and the product, \( P_b \), are \(-152\) kJ mol\(^{-1}\) and \(-345\) kJ mol\(^{-1}\), respectively (in reference to the separated reactants, Fig. 4). \( R_b \) appears relatively more stable than \( P_b \). Activation barrier via pathway b is lower by 31 kJ mol\(^{-1}\) than that along pathway a. This indicates that, the linear chain cluster of alumina is catalytically more active in producing phenolate than the cyclic dehydrated cluster.

Test computations employing the dependence of the reactivity of alumina cluster on the cluster size has been considered. We investigated physisorption and chemisorption interactions of phenol with the larger \((\text{Al}_2\text{O}_3)_n\) reported in the literature.44

Fig. 4  Optimised geometries for species in the reaction of phenol with dehydrated alumina clusters. Values (in kJ mol\(^{-1}\)) of energies are in reference to physisorbed reactant.
Stable optimised structures are shown in Fig. 5 calculated binding energies of the physisorbed and the chemisorbed structures are $-150 \text{ kJ mol}^{-1}$ and $-315 \text{ kJ mol}^{-1}$, respectively, both values are in a good agreement with the corresponding values we obtained for the smaller dehydrated clusters (i.e., $-129$ to $-152 \text{ kJ mol}^{-1}$ and $-241$ to $-345 \text{ kJ mol}^{-1}$, respectively). Furthermore, binding energies obtained for the larger (Al$_2$O$_3$)$_n$ cluster are consistent with the calculated binding energies in our recent study$^{31}$ for the interaction of phenol with a seven-layer slab of the $2 \times 2$ (0001) surface alumina ($-127 \text{ kJ mol}^{-1}$ to $-202 \text{ kJ mol}^{-1}$). Thus, it can be concluded that energies of the surface interaction of phenol with alumina surface do not display sensitivity toward the cluster size. The same observation has been observed by Pan et al.$^{65}$ in their study of the reaction of 2-chlorophenol over the dehydrated and hydroxylated silica clusters with (SiO$_2$)$_n$ and (SiO$_2$)$_{18}$ clusters. They have found that binding energies of reactants and products using both structures are within (0.4–17.4) kJ mol$^{-1}$.

3.3. Reaction of phenol with Al$_2$O$_3$·nH$_2$O cluster

We now turn our attention to investigate the interaction of a phenol molecule with hydrated alumina clusters entailing different hydroxylation coverages, (i.e., all the hydrated alumina clusters shown in Fig. 3). The detailed mechanism of the interaction is presented in Scheme 1. Fig. 6 depicts optimised geometries of reactants, transition states, and products; along with their energy profiles.

First, we have studied the interaction of a phenol molecule with the (c) structure, Fig. 3. Three possible pathways have been considered, denoted as c$_1$, c$_2$ and c$_3$ in Scheme 1. As Scheme 1 demonstrates, these reaction pathways characterise (i) fission of hydroxyl’s bond over the same Al$_2$O$_3$ bond (bridging bond), (ii) H$_2$O elimination mechanism over the same Al–OH bond (1,2 non-bridging) and (iii) H$_2$O elimination route over two Al–OH bonds (1,4 non-bridging linkage), respectively (Fig. 3 illustrates atomic numberings). The reaction is initiated by the physisorbed-type interaction between O$_{phenol}$ and Al$_{cluster}$ via binding spacings of 2.007 Å, 1.979 Å and 1.997 Å in the reactants $R_n$, $R_c$ and $R_s$, respectively (Fig. 6). Calculated binding energies of the three reactants stand at $-143 \text{ kJ mol}^{-1}$, $-147 \text{ kJ mol}^{-1}$ and $-129 \text{ kJ mol}^{-1}$, respectively (in reference to the separated reactants). Regarding to the structural changes induced to the cluster; we observe that Al$_2$O$_2$ bridging bond in Fig. 6, $R_s$ elongates by 2.4% when compared with the corresponding value in the Fig. 3(c) structure while Al$_2$O$_2$ in $R_c$ and Fig. 6, $R_s$ increases by 8.1% and 8.2%, respectively. Dissociative desorption of phenol via these pathways leads to the formation of $P_{c_1}$, $P_{c_2}$ and $P_{c_3}$ (Fig. 6) intermediates with reaction energies of $-225 \text{ kJ}$, $-167 \text{ kJ mol}^{-1}$ and $17 \text{ kJ mol}^{-1}$, respectively. The thermodynamic penalty associated with the product $P_{c_3}$ most likely stem from the low coordinated Al$_1$ that display a 2-fold coordination.$^{66}$

Next, we examine the dissociative adsorption of phenol over the Fig. 3(g) structure. The reaction proceeds via the active Al=O double bond site of the cluster. We found a slight increase in the O–H bond length of the physisorbed phenol in pathway g (1.009 Å, Scheme 1), in reference to the gas phase value (0.97 Å). The corridor g in Scheme 1 characterises fission of the O–H bond in the phenol molecule in a noticeably exothermic reaction of 360 kJ mol$^{-1}$. The physisorbed state Fig. 6 ($R_c$) in this channel resides 166 kJ mol$^{-1}$ below the separated reactants. Compared to Fig. 3(d), the size of hydrated alumina cluster (g) with one water molecule is smaller and it has a planner structure. Therefore, as temperature increases, molecules move faster and they are more likely to collide and hence positively affect the collision frequency, $A$.

Reaction pathways c$_1$, c$_2$ and g proceeds via modest energy barriers of 71 kJ mol$^{-1}$, 104 kJ mol$^{-1}$ and 23 kJ mol$^{-1}$, respectively, whereas pathway c$_3$ incurs a very sizable energy barrier of 289 kJ mol$^{-1}$. Three concluding remarks can be drawn from values in Fig. 6. First, within Al$_2$O$_3$·2H$_2$O system (i.e.; pathways: g, c$_1$, c$_2$, c$_3$), as expected, reaction pathway g is the most favourable channel, presumably due to the presence of the active Al=O double bond site. Second, phenol dissociation catalysed/accompanied with water elimination (pathways c$_2$ and c$_3$) is more energy demanding than phenol decomposition through surface-assisted fission of its hydroxyl O–H bond (pathways c$_1$). For instance, the activation energy in pathway c$_1$ is lower by $33 \text{ kJ mol}^{-1}$ than that along pathway c$_2$. Third, the activation energy in reaction pathway c$_3$ as well as the calculated binding energy of the product $P_{c_3}$ are higher when contrasted with the corresponding values in pathway c$_2$, this indicates that water elimination preferably occurs at the same A-OH linkage; i.e., 1.2-elimination step rather than at different A-OH sites (i.e., 1,4-elimination). This has prompted us to exclude this mechanism (i.e., pathway c$_3$) from further consideration in our subsequent discussion.

Phenol interaction with higher hydrated alumina clusters (Al$_2$O$_3$·2H$_2$O (d) and Al$_2$O$_3$·3H$_2$O Fig. 3(e)) is presented in pathways d and e in Scheme 1, with Fig. 7 illustrates optimised geometries and relative energies for species involved in pathways d and e.

Water elimination via pathways d and e (Scheme 1) results in the formation of a phenololate moiety via activation barriers of 110 kJ mol$^{-1}$ and 142 kJ mol$^{-1}$, respectively. Pathways d and e characterise dissociative adsorption of phenol via water elimination through 1,2-route; i.e., attachment of the phenoxyO at
the Al atom and the simultaneous departure of the OH group attached to the same Al atom with the hydroxyl'H as a water molecule. Higher energy barrier for pathway e in reference to pathways c2 and d can be rationalised in energy penalty required for the rupture of the Al–O linkage in the former. The degree of hydration of alumina; could be viewed as a factor that partially dictates the catalytic activity of alumina via controlling the surface-acid properties. In this regard, Al atom in structure (e) (the Al2O3 3H2O system), is coordinated by four hydroxyl groups, whereas Al atom in c2 and d, is less coordinated presenting more acidic structures as illustrated in Scheme 2. From the scheme, we can see that, the addition of water molecule in the structure dblocks the Lewis active site and accordingly decreases the catalytic activity of the cluster. This view is supported by Digne et al. who argued that the lower the Al atom coordination, the stronger – the Lewis acidity. Calculated atomic Mullikan charges on Al atom for (c), (d) and (e) were shown to have more positive values on the four coordinated Al atom of 1.69e (structure (e)) when compared to the three coordinated Al atom (i.e., 1.52e in structures (c) and (d)). A positive correlation is found between the calculated energy barrier and calculated Mulliken atomic charges; i.e., the higher the atomic charges on Al atom, the higher energy required to break Al–OH bond toward generating water molecule (accompanied with the dissociative adsorption of phenol). Thus, the observed increase in barrier for pathway e in reference to pathways c2 and

Scheme 1 Reaction of phenol with the hydrated Al2O3 cluster. The highlighted reactions proceed via H2O elimination (presenting H2O elimination mechanism over the same Al–OH bond (1,2 non-bridging)).
d correlates with partial atomic charges; i.e., a prominent electronic descriptor that determines the acidity character.

Overall, we can compare between hydrated and dehydrated alumina from two different perspectives. First, within fission of hydroxyl’s bond reactions over the same Al–O bond; contrasting pathway Fig. 6 c1 with pathway a reveals that, the energy barrier required in hydrated alumina clusters (i.e.; $c_1 = 71$ kJ mol$^{-1}$) are significantly higher than that over the dehydrated one (i.e.; $a = 41$ kJ mol$^{-1}$), respectively. Second, saturation of Al–O double bonds in the course of the hydroxylation of cluster b into d (refer to Fig. 3) significantly increases the barrier required for water elimination from only 10 kJ mol$^{-1}$ to 110 kJ mol$^{-1}$. Together, these findings indicate that dehydrated alumina cluster are more active in producing phenolate than hydrated alumina clusters. This observation agrees with the findings of Pan et al.$^{65}$ who found that, the dehydrated silica cluster (with the presence of two ends of S–O double bonds sites) produces chlorophenolate from 2-chlorophenol through an energy barrier of only 21 kJ mol$^{-1}$, compared with 70 kJ mol$^{-1}$ over the hydrated cluster (the same cluster after the two Si–O double bonds sites become saturated).

The most obvious finding to emerge from inspection of data in Table 1 is that, in both hydrated and dehydrated alumina, the dissociated product via Al–O double bonds site of the cluster is more stable than that leading to Al–O bond cleaving. For example, reaction energies that mark the formation of $P_g$ and $P_b$ (double bonds sites) amount to $\pm 360$ kJ mol$^{-1}$ and $\pm 345$ kJ mol$^{-1}$, respectively, while the analogous energies of $P_c$ and $P_a$ are $\pm 225$ kJ mol$^{-1}$ and $\pm 241$ kJ mol$^{-1}$, (A–O bond fission), respectively. This finding is in agreement with those obtained by Pan et al.$^{65}$ The authors found that dissociative adsorption of 2-chlorophenol through rupture of its hydroxyl’s bond over a S–O double bonds site forms more stable product by 136 kJ mol$^{-1}$ than that leading to Si–O bond cleaving.

Desorption of the phenolate moiety from both dehydrated alumina cluster and hydrated alumina clusters, was found to be highly endothermic by 334–373 kJ mol$^{-1}$. This finding is in
accord with those reported in our recent study for the interaction of phenol and chlorophenol molecules over alumina surfaces and silica clusters, 394 kJ mol$^{-1}$ and 379 kJ mol$^{-1}$ respectively. This profound stability of phenolate enables it to undergo bimolecular reactions via the so called Eley–Rideal (ER) and Langmuir–Hinshelwood (LH) mechanisms to produce dibenzo-p-dioxin and dibenzofuran; respectively. In alternative corridor, decomposition of phenolate on the surface is expected to initiate the formation of soot.

3.4. Kinetic consideration

We conclude the study by implementing a microkinetic analysis of the abovementioned reactions in this study. Fig. 8 represents Arrhenius plots while Table 2 displays the calculated reaction rate parameters. Within the considered temperature limit, reactions pathway c$_2$ displays the highest activation energy and relatively high dependence on temperature. For all reactions, the fitted Arrhenius energy of activation ($E_a$) largely reflects corresponding energy barriers presented in Fig. 3, 6 and 7. Calculations of the conversion-temperature profiles were carried out based on a simplified plug flow reactor (PFR) model. The material balance equations were solved by Polymath software:

$$r_B = -r_A = \frac{d(F)}{d(W)}$$  (3)

Addition of a water molecule to alumina cluster blocks the active Lewis acid site.

Scheme 2 Structure of acidic and basic site of alumina cluster.
In the considered reaction, \((A \rightarrow B)\), \(A\) and \(B\) represents the molecularly adsorbed phenol and the dissociative structures; respectively. \(r\) denotes the reaction rate, \(F\) symbolizes the molar flow rate of phenol in mol s\(^{-1}\), and \(W\) stands for alumina catalyst weight in kg. The reaction is considered to be first order with respect to phenol. The model utilizes reaction rate constants given in Table 2. The catalytic destruction of phenol molecule over \(\text{Al}_2\text{O}_3\cdot n\text{H}_2\text{O}\) catalysts as a function of temperature is presented in Fig. 9. It can be seen that all hydrated coverage of alumina clusters exhibits a highly catalytic destruction activity for phenol molecule, evident by high conversion at low temperatures. Calculated temperature of 90% destruction of phenol molecule \(\left(T_{90}\right)\) occurs at 350 K, 925 K, 425 K and 425 K for pathways c\(_2\), c\(_3\), d and e, respectively. To the best of our knowledge, literature provides no conversion values pertinent to interaction of phenol with \(\alpha\)-\(\text{Al}_2\text{O}_3\). Considering the very high desorption energy for phenolate, formation of gas

phase phenoxy should be hindered. The LR and LH mechanisms operated by the highly stable surface-bounded phenolate species, remains largely speculative.

4. Conclusion

This study sets out to assess the effect of surface acidity on the interaction of alumina with phenol molecules. Interaction of phenol molecule with dehydrated alumina clusters proceeds via fission of the hydroxyl’s bond over either Al–O single bond or Al=O double bond. Clusters with the active Al=O double bond (i.e., b) are catalytically more active in producing phenolate when compared to structures where all bonds are saturated (i.e., a, Al–O single bonds). Overall, c channels that proceeds through fission of the hydroxyl’s bond over Al–O (i.e.; c1) are more feasible than those proceeding via H2O elimination routes (i.e.; c2 and c3). The most obvious finding to emerge from this study is that adding water molecules increases the coordination of Al atoms and acts to block available Lewis acid sites for uptake of phenol molecules. Simplified kinetics model suggests dissociation of phenol molecules at low temperatures; however, subsequent desorption of adsorbed phenolate into gas phase phenoxy radicals is hindered by very sizable desorption energies.
