Characterization of the adsorption dynamics of trisodium citrate on gold in water solution†

Susanna Monti, ^a Giovanni Barcaro, ^b Luca Sementa, ^b Vincenzo Carravetta ^b and Hans Ågren ^{cd}

Molecular dynamics simulations (MDs) based on a reactive force field (ReaxFF) are carried out to investigate typical adsorption modes of trisodium citrate (CIT) on gold nanoparticles (AuNPs). All possible configurations of CIT on a model AuNP in solution are identified and the stabilizing role played by the adsorbate on the AuNP structure is disclosed by analyzing protonation state, dynamics and interactions of the molecules with the surrounding environment. A realistic scenario is created by sampling extensively the conformational space of citrate and by validating the simulation results against data extracted from the literature. Carboxyl moieties are found in contact with the gold substrate through one or both oxygens and Na^+ ions are present in the adsorbed citrate layer. Citrate binding is relatively strong and its action as a chelator stabilizes surface reconstructions. The molecules have the tendency to self-assemble and form a stable cover, which is reinforced by adatoms. All the results are in perfect agreement with experimental observations and theoretical data.

Introduction

Over the last few years a great variety of experimental and theoretical investigations have focused on gold-based nanomaterials for developing effectively tuned cancer therapies, local drug delivering agents, efficient detectors and specific bio-sensors.^{1–4} All these studies tried to disclose, at the nanoscale level, structure, dynamics and physicochemical properties of different types of hybrid systems in order to suggest modifications and new design strategies to improve their performance. Gold nanoparticles (AuNPs) are very promising vehicles, efficient radio-sensitisers and can be used as photothermal and contrast agents.^{5,6}

The selection of specific AuNPs morphologies is fundamental for the target application and it is often made on the basis of the nanoparticle dynamics and response. For example, due to the enhanced signals, spiky structures and irregular shapes are preferred to spherical conformations for *in vivo* experiments, whereas spherical forms are the ideal choice for

immune-gold labeling and lateral flow tests.^{7–10} As a matter of fact, specific AuNP structures can be obtained by biasing the first steps of their preparation with suitable substances and by modulating the environmental conditions. This has been reported in a large number of books, reviews and articles, where production, properties and applications are exhaustively described (see ref. 11–19 and references therein).

All of these papers agree in defining the seed-mediated growth method as one of the most widespread techniques for synthesizing the nanoparticles, with a thorough control of their shape and size, and citrate as one of the leading compounds (citric acid reduction reactions) and stabilizing agent. The role played by citrate is recognized and attributed to its electrostatic attributes.²⁰ Indeed, the stabilization is essentially due to the mutual repulsion between neighboring AuNPs that is caused by the negative surface charge of the citrate layer. According to earlier publications, the layer thickness is around 0.4–0.7 nm (ref. 21) and the citrate-to-gold ratio²² can be changed to adjust the size of the final carriers.

Disclosing the intermolecular interactions (gold–adsorbate and adsorbate–adsorbate interactions) together with the adsorbates structure and dynamics at the interface is very important for correlating these features with the changes in the physicochemical properties of the nanoparticle materials and their stability in solution.^{23,24}

By means of classical molecular dynamics based on ReaxFF^{25–29} we depict comprehensively citrate adsorption on gold by including explicit solvent molecules (water and sodium counterions), a realistic representation of the metal support (a 3 nm AuNP), a coating multilayer, reactivity and dynamics of

† Electronic supplementary information (ESI) available: Citrate speciation plot, potential energy trend during equilibration/production, Au–O minimum distance distribution. See DOI: [10.1039/c7ra10759e](https://doi.org/10.1039/c7ra10759e)

all the species. The behavior in solution of the model AuNP coated with at least a monolayer of citrate molecules is disclosed considering both acidic and basic conditions. No restraints are introduced and all species can interact with each other and modify their conformation in response to the environment. This is an application of the methodology we have developed and used successfully in previous studies.³⁰⁻³³

Computational details

Model building and system setup

The coordinates of the metal support were extracted from an earlier study³² where the adsorption mechanism of cysteine onto an AuNP in solution was investigated exhaustively. The chosen model was an equilibrated structure composed of 887 Au atoms with a truncated octahedron shape. Its maximum diameter was around 3 nm and the low index (111), (100) and (110) facets were all available for binding. As already observed,³² due to the size of the system, the extension of these regions was limited and thus each of them could host three or four molecules at most. In order to decorate the surface randomly, the AuNP was surrounded by a shell of sparse citrate units (90 in all), which were sufficient to cover the whole interface. These molecules were placed relatively far from the AuNP (with minimum distance around 6 Å) so that the added water could penetrate the enveloping citrate layer and reach the surface. Then, the complex was solvated by water molecules (around 14 000) and Na⁺ counterions (total number of atoms in the system: 43 551). Acidic and basic pH conditions were simulated considering two different ideal starting configurations: one where all the citrates were (−3) anions and the other one where all the molecules were doubly deprotonated (−2). In both cases they were neutralized by the required number of Na⁺ counterions (270 or 180). According to the table reported in ref. 34 at a pH = 7 citric acid is nearly completely dissociated (−3 anions), whereas at acidic pH all the other species prevail.³⁴ The final simulation box after equilibration was about 8 × 8 × 8 nm³.

The starting conformation of citric acid was obtained from a DFT/B3LYP/6-311++G(d,p) level optimization in the gas phase. Minimum energy structures and torsional energy barriers necessary to describe correctly this type of molecule were included in the original parametrization of the protein force field and tested for several different structures.²⁹

Reactive molecular dynamics simulations based on the force field developed in ref. 31 were performed, first, in the NVT ensemble at $T = 300$ K for about 50 ps and then in the NPT ensemble for about 50 ps to get the correct density. The whole time period (around 100 ps) was sufficient to equilibrate the system at the selected temperature. In this phase, almost all the molecules (around 40%) that were in a favorable orientation settled on the surface, whereas the other 60%, more solvated and interconnected by hydrogen bonds, remained in the outer regions. Their motion toward the support and conformational rearrangement was slower but was completed in the subsequent 100 ps of the production stage, which was carried out in the NVT ensemble. These initial steps were not included in the final analysis. The sampling phase started afterwards and was

extended for 1000 more picoseconds. System snapshots were saved every 0.025 ps and a total of 3 600 000 configurations of the citric acid molecule were collected and analyzed. Temperature was controlled through the Berendsen's thermostat³⁵ with a relaxation constant of 0.1 ps and the time step was set to 0.25 fs. The trajectories were examined focusing on species, adsorption modes, molecular conformations, coordination numbers, atom–atom radial distribution functions (RDFs) and various types of distances. In order to analyze the protonation states of the citrate molecules an O–H cutoff distance of 1.15 Å was considered. The Amsterdam Density Functional (ADF)³⁶ and LAMMPS codes³⁷ were employed for all the simulations.

Results and discussion

Molecular species

In the final configuration extracted from the MD trajectories, the AuNP surface is partially covered (60% at most) with adsorbed citrate molecules that adopt a great variety of orientations. These were classified according to the connections of the carboxyl oxygens to the interface, namely monodentate and bidentate coordinations or a combination of the two (Fig. 1 and 2). The binding modes were directly correlated not only to the final species existent in the system that evolved just because of the chosen general conditions (pH), but also to local reorganizations due to surface reconstructions, citrate self-interactions, sodium ions relocations and perturbations induced by water. Before discussing the type of adsorption it is thus appropriate to analyze the resulting species and their location in relation to the support.

A common trait shared by the two simulations is that the hydroxyl group of the citrate remains intact for the whole sampling time, in line with its estimated ionization pK_a (around 14.4),³⁸ whereas the carboxyl protons are readily dissociable. In the first simulation, corresponding to a basic solution, the cit(−3) molecules, which are the only citrate species at the beginning of the simulation, are partially converted to other protonated species, namely cit(−3) (60%), Hcit(−2) (30%), H₂cit(−1) (10%). A similar behavior was previously suggested by a study of an aqueous solution of cysteine.³⁹ There, the interactions at the water/air interface generated proton exchanges that lead to a local chemical composition quite different from the bulk. In the second simulation reported in the present study it is observed that starting from 100% of Hcit(−2), which roughly represents an acidic solution, the equilibrium composition around the AuNP is predicted as cit(−3) (35%), Hcit(−2) (40%), H₂cit(−1) (20%) and the appearance of completely protonated citric acid molecules (5%) is also observed. This distribution of the species does not correspond to a definite pH suggesting that reference titration curves and pH cannot be used for these specific conditions, which are the results of local effects. Indeed, the analysis of the species indicates that speciation depends on the location of the molecules and is strongly influenced by their attachment to the AuNP. This is especially apparent in the case of acidic pH. A similar behavior was observed previously for other systems, *i.e.* in the case of TiO₂ nanoparticles⁴⁰ and for citrate adlayers on AuNPs through

Fig. 1 Typical coordination modes of one carboxyl group to the gold interface. Configurations extracted from the final sampled geometry. The green lines indicate distances lower than 2.6 Å. Au–O separations are around 2.3 Å.

FTIR and XPS analyses.^{41,42} To check that this behavior is due to the adsorption on the AuNP, we restricted the analysis of the molecular dynamics simulations to the citrate species farther from the nanoparticle, thus to an environment close to a pure solution. In this case the predicted ratios for citrate anions are in reasonable agreement with the experimental ones, specified by the titration curves, with a deviation of less than 10%.

Adsorption mode

As far as the binding mode is concerned, 50% of the adsorbates were connected to the top gold layer through the coordination of just one of the terminus carboxyl group, whereas the other

Fig. 2 Typical coordination modes of two carboxyl groups to the gold interface. Configurations extracted from the final sampled geometry. Most of the surrounding molecules have been removed for clarity. Na^+ ions are orange spheres and some of the water molecules surrounding the adsorbate are displayed as blue slim sticks. The green lines indicate distances lower than 2.6 Å. Au–O separations are around 2.3 Å.

50% were adsorbed through both the central and a terminus moieties, thus resulting in a stronger attachment to the metal support. Representative configurations of the adsorbed molecules are shown in Fig. 3–5. It was noticed that structures bound to the interface by means of all the three carboxyl units were rarely present and mainly consisted of chelate formations. A common arrangement is the one shown in the top right picture of Fig. 6. There, two carboxyl groups of the molecule (middle and terminus moieties) with the help of the hydroxyl oxygen entrap a gold adatom, while the other carboxyl terminus is coordinated through one of its oxygens to the surface. In the picture on the left hand side, instead, the enveloping mechanism is double but the connection of the citrate to the surface seems relatively weaker. Finally, the bottom picture of Fig. 6 shows the complex organization of the various adsorbates on the surface, the formed staple motifs (gold atoms captured by

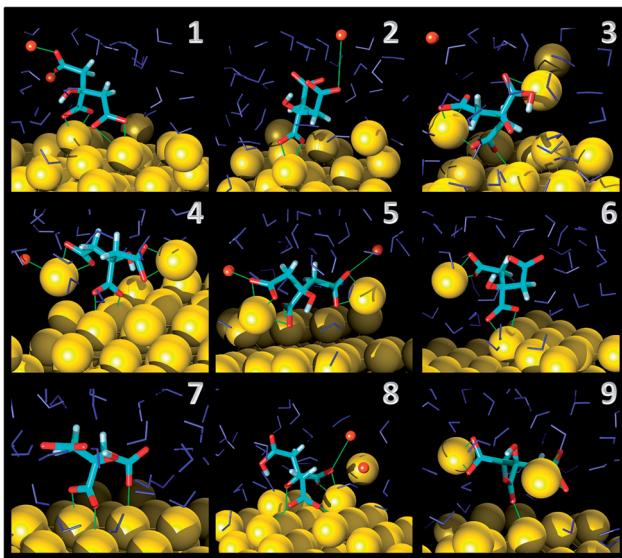

Fig. 3 Selected adsorbate configurations.

Fig. 4 Selected adsorbate configurations.

two different adsorbed molecules), interactions with ions, molecules in solution interacting with the deposited layer. This is just a small portion of a very complex scenario where many possible configurations are probable as demonstrated in several studies.^{41,43}

Even though the dominant adsorption in both acidic and basic simulations was realized through one of the terminus carboxyl groups (with a probability of 85% and 75% for the acidic and basic cases, respectively), a slight reduction (to around 10%) of these species and the simultaneous increase in the central group coordination (with a probability of 15% and 25% for the acidic and basic cases, respectively), was observed for acidic conditions. Most probably, the protonation of the terminus sites discouraged their binding to the surface but

Fig. 5 Selected adsorbate configurations.

Fig. 6 Typical adsorption modes of chelating agents. Configurations extracted from the final sampled geometry. Most of the surrounding molecules have been removed for clarity. favored their extension towards the outer solution (solvent or citrate molecules far from the metal interface).

The complexity of the structural arrangement of the adsorbed citrate layers on AuNPs was analyzed in various studies^{41,42} and it was concluded that many different schemes were possible simultaneously. It was proposed that the lowest pK_a carboxyl group (middle moiety) plays a crucial role in the conformation of the adsorbed molecules and it was most

preferentially bound to the surface by coordinating its carboxyl oxygens, while one of the other two terminus moieties could be adsorbed or not.

This is partially consistent with our results, which exclude the single binding option because statistically less significant. In fact, due to the conformational characteristics of this acid, *i.e.* the closeness of the terminus groups to the central moiety, there was a marked tendency to engage also one of the end groups in interactions with the surface. In the present simulations this cooperation (terminus + central) seemed more favorable, in agreement with other studies.^{44–46} Furthermore, in line with the results of ref. 41 (see Fig. 6 and 3–5) part of the attached molecules extended the uncoordinated groups toward the neighboring species farther from the surface and formed interconnected networks. These new associations together with the captured adatom complexes determined an increase in the thickness of the coverage (which was around 7–8 Å). The agreement with the data reported by J.-W. Park and J. S. Shumaker-Parry,⁴¹ who estimated the thickness of the citrate layer on the basis of the interaction of the particles functionalized with alkanedithiol chains, is very good. They concluded that the minimum thickness could fall in a range around 6.5 Å and that the effective depth was approximately 8–10 Å.

Fig. 7 Normalized atom–atom radial distribution functions of: citrate oxygens–citrate oxygens, citrate oxygens–Au, citrate oxygens–Na⁺, Au–water oxygen, Au–Na⁺. (A) Basic pH simulation. (B) Acidic pH simulation.

Examination of the atom–atom radial distribution functions of the citrate oxygens with all the other atoms of the system can be useful to compare the behavior of the molecule in the two different pH conditions, to check self-interactions and to determine the location of the adsorbate in relation to the support. The normalized RDF plots are shown in Fig. 7.

As it can be noticed, the trends obtained for the two simulations are strikingly similar suggesting that the observed population differences (discussed above) did not influence the binding behavior of the molecule. We could speculate that the final populations for the acidic conditions are influenced by the binding to the AuNP. The two O(citrate)–O(citrate) and O(citrate)–Na⁺ sharp peaks centered at about 2.25 Å confirmed self-interactions of the molecules and their coordination to sodium ions (evidenced also in most of the images depicting the adsorbates) independently of their location (*i.e.* in solution or on the AuNP surface). The lower O(citrate)–Au peak located at around 2.4 Å indicates coordination to gold and its height suggests that only a portion of the molecules is stably adsorbed. Moreover, water oxygens and Na⁺ ions remain farther from the

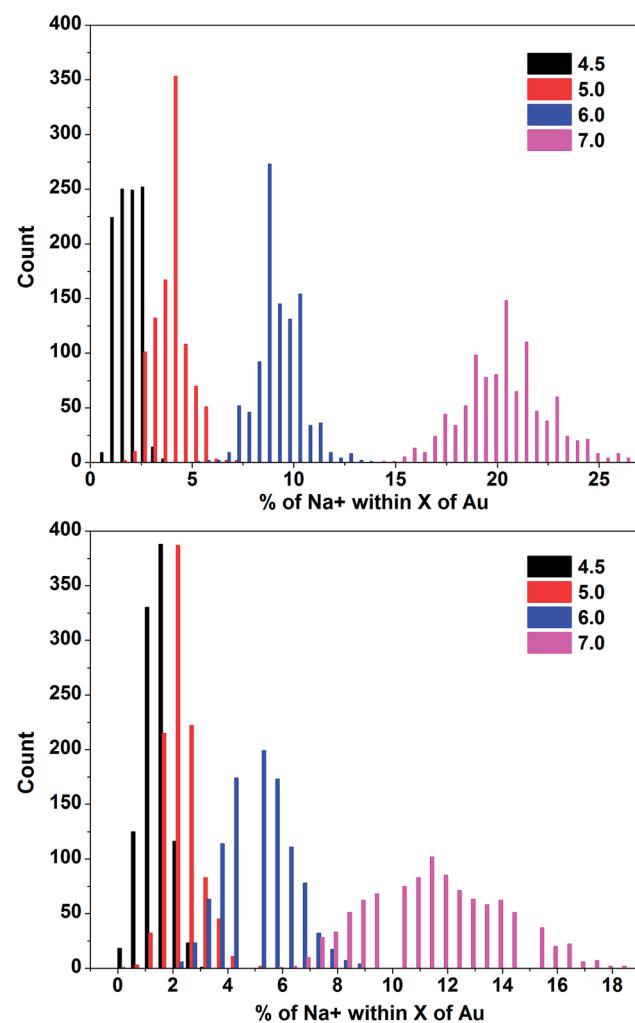

Fig. 8 Distributions of the percentage of Na⁺ ions within 4.5, 5.0, 6.0 and 7.0 Å of Au. (Top) Basic pH simulation. (Bottom) Acidic pH simulation.

surface in relation to the citrate oxygen (at 2.8 and 4.3 Å, respectively).

The strength of the adsorption on gold and the coordination of the carboxyl oxygens to Na^+ was estimated by inspecting the coordination numbers for $\text{O}(\text{citrate})\text{-Au}$ and $\text{O}(\text{citrate})\text{-Na}^+$ distances lower than 3 Å and percentage of occupation of these states during the last 100 ps of the production. In the case of gold, the result suggested that most probably (76%) one or two Au atoms were found coordinated to the carboxyl oxygens in 80% of the configurations, whereas for 3 Au atoms the probability decreased to 10% and the occupation of these states was also reduced (55%).

These reactive simulations were capable of identifying a great variety of gold–citrate interactions ranging from weak to strong coupling, namely physisorption to chemisorption. However, it was not straightforward to discriminate between them just because many intermediate situations were present.

The results suggest that the strongest couplings were those where the Au–O distance was about 2.10–2.12 Å, which could be identified with effective chemisorbed species. Then, slightly weaker adsorption were found for oxygen–Au distances in the range 2.23–2.30 Å (in Fig. S3† is shown the distribution of Au–O minimum distance).

As far as Na^+ is concerned, the probability of finding one or two ions within 3 Å of the adsorbed citrate oxygen was 36% in the basic pH simulation but moderately lower (27%) for the acid pH, with a comparable occupation of 60%.

In order to explore further the presence of the sodium ions in the first layer around the AuNP (between 4.5 and 7 Å) the distribution of the percentage of ions in different shells was calculated from the final 100 ps of the two simulations (Fig. 8). In line with the other data many more ions were found within 7 Å of the AuNP in the basic simulation suggesting, as expected, that a more negatively charged environment is obtained in this case.

Fig. 9 Distributions of the torsional angles of the sampled molecules during the dynamics. (Left) Basic pH simulations. (Right) Acidic pH simulations. Different colors refer to different frames sampled from the last part of the production trajectory.

Molecular flexibility

The conformational characteristics of the molecule were analyzed considering the two main torsional angles defining the position of the carboxyl groups (Fig. 9). These were investigated in another study⁴⁷ to determine the conformers of citric acid in the gas phase and in solution and probe the effects due to different pH on its adsorption on NaCl. The torsion distributions of the molecules sampled in this study are displayed in Fig. 9.

Comparison with the data of the minimum energy conformations identified in ref. 47 reveals a perfect agreement with the peak values of the distributions, suggesting that the adsorption was not influential in shaping the structures. As it can be noticed, all the angles are equally explored by the two simulations. This is also in agreement with the experimental NMR data reported in ref. 24 regarding the conformation of the carbon backbone. They confirm that citrate retains the structure and hydration arrangement even when bound to the AuNP surface and only the carboxylate groups interacting directly with gold are perturbed.

Conclusion

The results of this investigation regarding the adsorption of trisodium citrate on a gold nanoparticle at two different pHs, which were realized by a different concentration of the initial species present in the system, suggest that the whole stabilizing mechanism arises from a combination of different concerted events. First, the direct adsorption of the molecule on the surface of the AuNP in a preferential fully deprotonated form confers stability to the metal support by altering its surface charge. The adsorption induces a modulation of the local conditions, which do not correspond any longer to the tabulated values for a pure solution. The adsorption of the citrate consists of a strong coordination of the carboxyl oxygens to the surface that can involve one or more groups. Second, the chelating ability of the partially adsorbed molecules prevents the migration of the gold atoms emerged from the surface. These adatoms are entrapped in the covering layer and remain close to the nanoparticle interface. Consequently, citrate limits the extension of the surface reconstruction. Third, several citrate molecules on the interface are found interconnected through metal adatoms. These are characteristic substructures, named staple motifs, were already observed in the case of cysteine and cystine adsorption.^{32,33} Fourth, Na⁺ ions are found within the adsorbed monolayer in a region between 4–7 Å from the gold substrate in line with experiment.
