# A silver nanowire mesh overcoated protection layer with graphene oxide as a transparent electrode for flexible organic solar cells†

Byung-Yong Wang,<sup>a</sup> Eung-Seok Lee,<sup>a</sup> Young-Jei Oh<sup>\*b</sup> and Hyun Wook Kang<sup>ID \*c</sup>

For high-throughput flexible electronic devices to be ready for the market, their transparent conductive electrodes (TCEs) should show stable working performance during folding conditions and have a long operating life. In this study, TCEs were produced by over-coating silver nanowire (AgNW) electrodes with graphene oxide (GO). The GO/AgNW electrodes showed an outstanding sheet resistance value of  $18 \Omega^{-1}$ , 87% transmittance, mechanical stability, and excellent long-term stability. Furthermore, the GO film wrapped around the AgNWs, which improved the inter-nanowire junction resistance and lowered the surface roughness without any heat treatments or high-force pressing processes. Flexible P3HT:PC<sub>60</sub>BM- and PTB7:PC<sub>70</sub>BM-based organic solar cells (OSCs) were produced using the GO/AgNW transparent electrodes on a flexible polyethylene terephthalate substrate. The GO/AgNW electrode exhibited a higher optical absorption in all the OSCs compared to those of the indium tin oxide (ITO) electrodes and showed a high short circuit current of  $3 \text{ mA cm}^{-2}$ . Consequently, the fabricated OSCs showed a 7% higher efficiency than the ITO electrodes. In addition, after 50 bending tests, the efficiency of the GO/AgNW electrodes changed less than 3%. Thus, the GO/AgNW electrodes showed enhanced results in terms of resistance and durability compared to conventional transparent electrodes, including ITO-based electrodes.

## 1. Introduction

Organic solar cells (OSCs) offer a simple device structure, and they can be produced on a large scale by roll-to-roll processing on polymer substrates. As the interest in flexible solar cells increases, so does the demand for lightweight OSCs that can be freely bent or folded like paper. Moreover, the use of such flexible OSCs will allow design of devices that can be freely changed and will enable such devices to be fabricated for a curved surface and to be rolled like a roll of paper. Thus, OSCs can be used in various applications, including wearable electronic devices.<sup>1–6</sup> However, transparent electrodes with high conductivity and flexibility must be developed for OSCs to be flexible.

Currently, indium tin oxide (ITO) is widely used as a transparent electrode material due to its high electrical conductivity, excellent chemical stability, and high light transmittance, but it

is limited as a next-generation electrode because of its high price and inadequate indium resources. Another disadvantage of ITO film is its brittleness, which makes coating it onto a flexible plastic substrate difficult. Furthermore, it absorbs in the UV/blue region, which is a drawback when applied to solar cells. These problems motivate the development of new types of transparent conductive electrodes (TCEs). Conducting polymers, carbon nanotubes, graphene, and metal networks have all been investigated as alternatives to ITO.<sup>7–15</sup>

In the case of organic conducting polymers, electrical conductivity increases proportionally with electrode thickness. However, a thick electrode layer comes at the cost of decreased transmittance because conducting polymers absorb light in the visible region; thus, electrode films must be thinly coated (100 nm or less) with such polymers. Reaching a sheet resistance of  $80 \Omega^{-1}$  is difficult with a 100 nm-thick coating.<sup>16–18</sup> Another candidate for transparent electrodes is carbon nanotubes (CNTs), which exhibit excellent electrical conductivity and high transmittance, and achieving a low sheet resistance ( $10 \Omega^{-1}$ ) requires a large quantity of CNTs. Thus, the electrode becomes black while maintaining transparency results in decreased transmittance. In the case of transparent graphene electrodes, the defective bond between the graphene flakes and the current collector leads to high contact resistance and thus high sheet resistance.<sup>19,20</sup>

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c7ra10889c

To overcome these problems, silver nanowires (AgNWs) are arising as a next-generation material because they exhibit excellent electrical and optical characteristics, and they are easy to manufacture on a large scale and at a low cost through a solution process. In addition, flexibility can be easily achieved due to their long, thin morphology.<sup>21–28</sup>

However, this material is not free of problems. The biggest challenge is that AgNWs are oxidized by oxygen, which lowers the electrical conductivity and transparency. Another problem is that AgNW coatings easily separate from their substrate due to a low adhesive force.<sup>24,29–32</sup> Furthermore, when AgNWs are applied to the transparent electrode of solar cells, the high surface roughness of the AgNWs causes a low shunt resistance, high dark current, and low efficiency.<sup>33</sup> Thus, using AgNWs to fabricate high-efficiency optoelectronic devices has many drawbacks. To address these issues, innovative techniques have recently been reported for improving the adhesive force while lowering the surface roughness by adapting an over-coating layer (OCL) and protecting layer for the AgNWs using conducting polymers and oxides, such as zinc oxide (ZnO). These methods, however, require a thick coating as a top-coat material (conducting polymers, oxides, *etc.*) to lower the inherent surface roughness of the AgNWs, which also lowers the optical transmittance.

Therefore, in this report, a very thin graphene oxide (GO) layer whose transparency is not low was formed *via* spray coating to preventing the AgNW transparent electrode from oxidizing in air. The GO dispersion was hydrophilic due to its oxygen functional groups but was not electrically conductive.<sup>34–36</sup> As a result, a transparent electrode could be fabricated with low surface roughness and a high adhesive force, which featured a thin GO layer that could directly pass currents *via* tunneling, even though it is an insulator, thereby improving the electrical characteristics of the AgNWs.<sup>33</sup> Significantly, the AgNWs did not oxidize, even when exposed to the air for over two months. Furthermore, a flexible OSC was produced using a GO/AgNW transparent electrode on a polyethylene terephthalate (PET) substrate.<sup>37–39</sup>

## 2. Experiments

### 2.1 Preparation of a GO/AgNWs TCE

In this study, an ink was prepared with highly linear AgNWs with a thickness of 40 nm and a length of 45  $\mu\text{m}$ , which had been fabricated in a previous experiment. The ink was slot-die coated using a slot-die coater on a PET substrate. For the OCL, the GO (Angstrom Materials) with an X–Y dimension of 1  $\mu\text{m}$  or less and a thickness of 1–1.2 nm was used. First, 1 mg of GO was diluted in 10 mL of DI water, and a spray coater was used to prepare the coating. To remove the solvent, the substrate was heated to 110  $^{\circ}\text{C}$  during the experiment. The fabricated GO/AgNW transparent conductive film showed 87% light transmittance and a sheet resistance of  $18\ \Omega^{-1}$ , which is similar to the 90% light transmittance and  $12\ \Omega^{-1}$  sheet resistance of commercial ITO (JMC, South Korea) (Fig. 1). Even though GO is an insulator, if it is coated very thinly on the AgNWs, electrons can easily move through it by ohmic contact

Fig. 1 Total transmittance spectra of ITO- and GO/AgNW-coated films.

and direct tunneling (Fig. S1†). Furthermore, the GO that was used in this experiment had characteristic G- and D-band peaks at 1611 and 1356  $\text{cm}^{-1}$ , respectively, as shown in Fig. S2.† These peaks in the G- and D-bands grow as the amount of GO increases. Hence, the presence of GO can be verified in the OCL.

### 2.2 Fabrication of organic solar cells

OSCs were fabricated using the transparent GO/AgNW electrode. A poly-3,4-ethylenedioxythiophene–polystyrenesulfonate (PEDOT:PSS) bilayer (Clevios™ PH 1000 and P VP AI 4083, respectively) was spin-coated to a 100 nm thickness as a hole transport layer (HTL) on the GO/AgNW substrate. The PEDOT:PSS was mixed with methanol (Aldrich) at a 1 : 1 volume ratio, and this solution was spin-coated at 4000 rpm for 40 s and annealed at 130  $^{\circ}\text{C}$  for 30 min in a glove box. Then, 18 mg of P3HT (Rieke Metals, Inc.) and 10.8 mg of PC<sub>60</sub>BM were melted in 1 mL of chlorobenzene as an electron transport layer (ETL). The mixture was spun at 2500 rpm for 40 s and was thermally treated in a glove box at 150  $^{\circ}\text{C}$  for 10 min. In addition, OSCs with high power conversion efficiencies (PCEs) were fabricated using poly[4,8-bis[(2-ethylhexyl)oxy]benzo[1,2-*b*:4,5-*b'*]dithiophene-2,6-diyl][3-fluoro-2-[(2-ethylhexyl)carbonyl]thieno[3,4-*b'*]thiophenediyl] (PTB7) and [6,6]-phenyl-C<sub>71</sub>-butyric acid methyl ester (PC<sub>70</sub>BM), which are low-bandgap polymers. The fabrication method was identical to that of the P3HT:PC<sub>60</sub>BM system. PTB7:PC<sub>70</sub>BM (1-materials) was dissolved at a 1 : 1.5 weight ratio in chlorobenzene : 1,8-diiodooctane (97 : 3) before being spun at 1000 rpm for 40 s and then annealed at 50  $^{\circ}\text{C}$  for 10 min in a glove box.

Finally, the LiF/Al electron-collecting top electrode was subjected to thermal evaporation to produce the final OSCs, and the thickness of each layer was observed by transmission electron microscopy (TEM) (Fig. 2). A control OSC was fabricated with an ITO/glass electrode as a reference for comparison, and all the processes were carried out identically.

### 2.3 Material and device characterization

The sheet resistance of the GO/AgNW transparent electrode was measured with a Keithley 2400 source meter by a 4-point probe method, and the transmittance was analyzed by an ultraviolet-

Fig. 2 A schematic cross-sectional view of P3HT:PC<sub>60</sub>BM-based OSCs with GO/AgNW and the corresponding cross-sectional high-resolution transmission electron microscopy (HRTEM) image.

visible spectroscopy (Perkin Elmer UV/Vis spectrometer Lambda 18). The GO structure was analyzed using Raman spectrometry. The haze factor of the GO/AgNW film was measured with a commercial haze spectrometer (Sinco). The surface of the transparent electrode was analyzed with a scanning electron microscope (SEM; XL-30 EDAX, Philips, Netherlands) and an atomic force microscope (AFM; Digital Instruments Dimension 3100, equipped with a Nanoscope IV controller). To evaluate the flexibility of the transparent electrode, the GO/AgNW/PET and ITO/PET transparent electrodes were compared using a bending test machine (ZB-100, Z-Tech) at a radius of 10 mm for 10 000 cycles.

The performance of the OSCs fabricated with the GO/AgNW transparent electrodes was analyzed using an ORIEL solar

simulator with a 150 W light source. To achieve the AM 1.5 condition and  $100 \text{ mW cm}^{-2}$  intensity, the intensity of the reference light source was calibrated using a standard Si photodiode. The external quantum efficiency (EQE) was measured using an ORIEL IQE 200 system. In addition, a cross-section of the OSCs was observed with a transmission electron microscope (TEM; JEM 2100F) using a focused ion beam (FIB) milling technique.

#### 2.4 FDTD simulation methods

To compare the light-scattering characteristics of the AgNWs, a commercial finite difference time domain (FDTD) simulation tool (Lumerical Solution, Inc.) was used. For the simulation

Fig. 3 Transmission electron microscope (TEM) images of (a) AgNWs (b) a AgNW cross-section. (c) Lattice fringes and (d) selected area electron diffraction (SAED) pattern of the AgNWs.

mesh, a uniform size of 0.25 nm was used for all the directions. Furthermore, a 300–800 nm wavelength light source was used. To evaluate the characteristics of the laminated-structure OSCs, the thickness of each layer was set to be identical to the corresponding thickness in the actual device.

### 3. Results and discussion

The AgNWs were fabricated by the reported polyol method,<sup>40</sup> which is a simple method of synthesizing AgNWs by growing reduced Ag ions in the [111] direction using a capping agent. The crystal structure of the synthesized AgNWs was analyzed *via* X-ray diffraction (XRD), which showed (111), (200), and (220) crystalline peaks, indicating a face-centered cubic structure (JCPDS Card no. 89-3722), as shown in Fig. S3.† Furthermore, the AgNWs grew with a pentagonal cross-section, and the

Fig. 6 Variation in the resistance of the GO/AgNW film as a function of the number of bending cycles.

synthesized AgNWs had a diameter of 45 nm and a minimum length of 40  $\mu\text{m}$  (Fig. 3).

The AgNWs are thin and long and thus are easily oxidized because their surface-to-volume ratio is much greater than that of the bulk material. For this reason, when the AgNWs are exposed to the air without a protective layer, they quickly oxidize or corrode. Fig. 4 shows SEM results for the stability the AgNWs in air. As described above, when the AgNWs were coated with GO as a protective layer, the AgNWs showed no change even after two weeks. In contrast, when the AgNWs were used without a protective coating, they generally oxidized and

corroded. Furthermore, the high acidity and sulfur molecules of the conducting polymer PEDOT:PSS can both damage the AgNWs, which makes using this material as a transparent electrode for a long time difficult. However, when the long-term stability was tested, the AgNW with the GO protective layer showed excellent stability with no changes in resistance for two months in air. However, when the AgNWs were used without the protective layer, the electrode's resistance sharply increased after 10 days. When PEDOT:PSS was used as a protective layer, the resistance sharply increased after 3 days at rest. These increases in the resistance were due to oxidization and corrosion, as explained above. The AgNWs with the GO protective layer showed excellent long-term chemical stability, even after long-term exposure to air (Fig. 5).

As mentioned above, fabricating highly efficient optoelectronic devices, such as OSCs with AgNWs, is difficult due to the shunt resistance, high dark current, and low efficiency resulting from the high surface roughness of AgNWs.<sup>32</sup> When the roughness of a transparent electroconductive film coated with AgNWs alone was compared to that of the GO/AgNW electroconductive film (Fig. 4d and e), the former showed a high surface roughness of 46.8 nm due to the presence of the AgNWs and the empty spaces between them, whereas the latter showed a low surface roughness of 4.3 nm. The reason for the low surface roughness is that the empty spaces are filled with GO, as shown in the SEM image, which offsets the high roughness of the AgNWs.

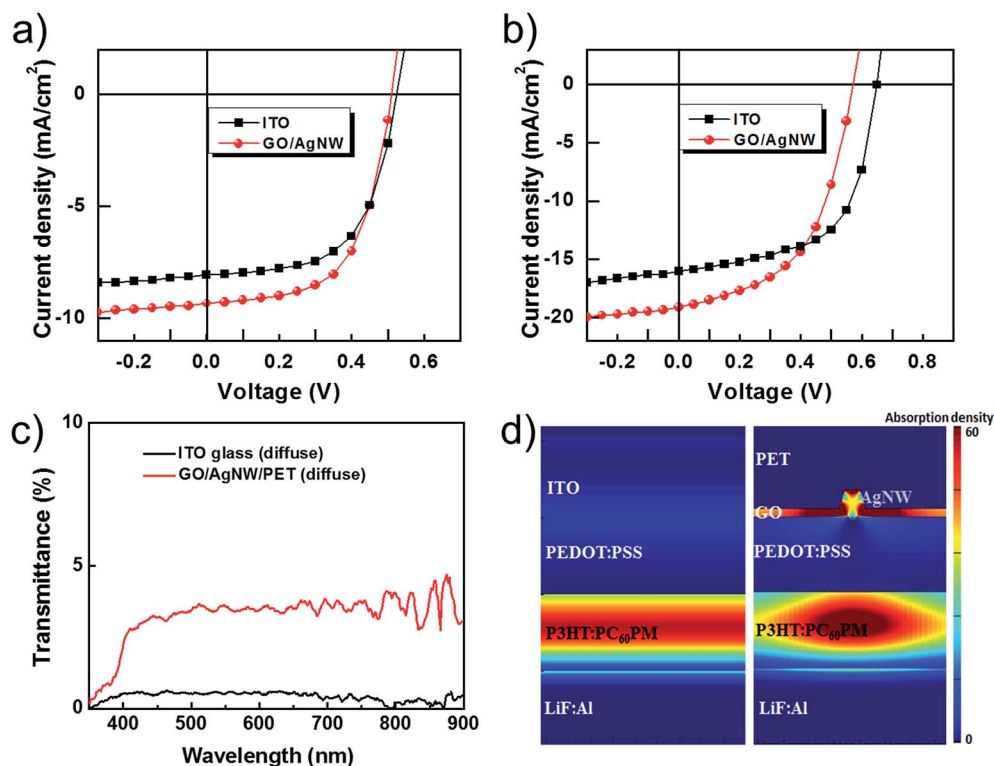

Fig. 7 Representative  $J$ - $V$  characteristics of P3HT:PC<sub>60</sub>BM and PTB7:PC<sub>70</sub>BM OSCs with the GO/AgNW mesh electrode and the reference device with the ITO electrode under AM 1.5 G illumination with 100  $\text{mW cm}^{-2}$  intensity. 	$V_{oc}$ (mV)	$J_{sc}$ (mA cm <sup>-2</sup> )	FF	PCE (%)
P3HT:PC <sub>60</sub> BM ITO (batch 1)	0.62 ± 0.00	7.97 ± 0.27	0.63 ± 0.02	3.18 ± 0.04 (3.27)
P3HT:PC <sub>60</sub> BM GO/AgNW (batch 1)	0.60 ± 0.00	9.17 ± 0.41	0.59 ± 0.00	3.25 ± 0.08 (3.32)
P3HT:PC <sub>60</sub> BM GO/AgNW (batch 2)	0.59 ± 0.01	9.53 ± 0.17	0.57 ± 0.01	3.26 ± 0.05 (3.31)
PTB7:PC <sub>70</sub> BM ITO (batch 1)	0.74 ± 0.00	16.32 ± 0.03	0.58 ± 0.01	7.14 ± 0.10 (7.27)
PTB7:PC <sub>70</sub> BM GO/AgNW (batch 1)	0.67 ± 0.01	19.79 ± 0.01	0.55 ± 0.01	7.32 ± 0.06 (7.38)
PTB7:PC <sub>70</sub> BM GO/AgNW (batch 2)	0.69 ± 0.00	18.15 ± 0.01	0.59 ± 0.01	7.53 ± 0.02 (7.56)
PTB7:PC <sub>70</sub> BM GO/AgNW (batch 3)	0.68 ± 0.00	19.84 ± 0.57	0.57 ± 0.01	7.62 ± 0.10 (7.66)

<sup>a</sup> Values from 3 and 4 devices were averaged, and the PCEs in parentheses indicate the highest values.

Furthermore, the GO/AgNW transparent electroconductive film showed excellent flexibility. The bending test demonstrated that due to the brittleness of ITO film, it cracked when the bending radius decreased, and the resistance sharply increased to at least 70% higher than the initial resistance. In contrast, for the GO/AgNW transparent electrode, the GO prevented the AgNWs from separating and losing contact with each other, and a small change in resistance of under 2% was observed, even after 10 000 cycles, indicating superior mechanical stability to that of the ITO transparent electrode (Fig. 6).

Fig. 7a and b and Table 1 show the results of the OSCs fabrication to verify the possibility of adapting the GO/AgNW transparent electrode as a flexible optoelectronic device. The commercial ITO on glass with 90% transmittance and a 12 Ω<sup>-1</sup> sheet resistance was compared with the GO/AgNW/PET transparent electrode with 87% transmittance and an 18 Ω<sup>-1</sup> sheet resistance. In the case of the P3HT:PCBM system, the ITO electrode showed an open-circuit voltage ( $V_{oc}$ ) of 0.62 ± 0.00 V, a short-circuit current ( $J_{sc}$ ) of 7.97 ± 0.27 mA cm<sup>-2</sup>, a fill factor (FF) of 0.63 ± 0.02, and a PCE of 3.18 ± 0.04% (highest: 3.27). The GO/AgNW electrode showed a  $V_{oc}$  of 0.60 ± 0.00 V, a  $J_{sc}$  of 9.17 ± 0.41 mA cm<sup>-2</sup>, an FF of 0.59 ± 0.00, and a PCE of 3.25 ± 0.08% (highest: 3.32). The  $J_{sc}$  of the GO/AgNW electrode was higher than that of the conventional ITO transparent electrode (Fig. 7a). In the PTB7:PC<sub>70</sub>BM-based system, the GO/AgNW electrode showed a  $V_{oc}$  of 0.68 ± 0.00 V, a  $J_{sc}$  of 19.84 ± 0.57 mA cm<sup>-2</sup>, an FF of 0.57 ± 0.01, and a PCE of 7.62 ± 0.10% (highest: 7.66), and its  $J_{sc}$  was higher than that of the ITO electrode (Fig. 7b). All three GO/AgNW electrodes showed the same trends. The details of the average performance parameter values of  $V_{oc}$ ,  $J_{sc}$ , FF, and PCE for all the devices are summarized in Table 1. All OSC performance metrics were averaged from the results of four devices.

The  $V_{oc}$  of OSCs is influenced by the sheet resistance and energy bandgap, and the  $J_{sc}$  is influenced by the transmittance. The higher the transmittance, the greater the light absorption becomes, which increases the  $J_{sc}$ . As shown in Fig. 7a and b and Table 1, the GO/AgNW electrode showed a low  $V_{oc}$  value in all the devices because its sheet resistance was higher by at least 6 Ω<sup>-1</sup> than that of the ITO electrode. The GO/AgNW electrode, however, showed an approximately 3 mA cm<sup>-2</sup> higher  $J_{sc}$ , even though its transmittance was lower by at least 3% than that of the ITO electrode.

The reason for this higher  $J_{sc}$  is the effect of the optical properties. As shown in Fig. 1, the spectra are similar to one another in the visible region, but the transmittance of GO/AgNW is higher in the 300–400 nm range and at 600 nm. As a result, more external photons are absorbed into the working layer of the device, which increases the phototransformation efficiency. In fact, measurements of the external quantum efficiency (EQE) indicate that higher phototransformation efficiency appears near 400 and 600 nm (Fig. S4†). Furthermore, the haze measurements show that the GO/AgNW has higher light scattering than ITO (Fig. 7c). This higher light scattering can be interpreted as a photon trapping effect, in which the photons discharged from the working layer that do not react with the photoactive material are reflected from the GO/AgNW layer and are returned to the working layer. The FDTD simulation result showed that the working layer absorbed more light, as shown in Fig. 7d. As described above, the efficiency of the OSCs increased as a result of the increase in the  $J_{sc}$  due to the increased light absorption, despite the low transmittance. Fig. 8

Fig. 8 Photographs of the continuous mechanical bending experiment of a P3HT:PC<sub>60</sub>BM OSC with the GO/AgNW mesh and selected  $J$ – $V$  characteristics during bending cycles up to 50.

shows the changes in the efficiency of the fabricated OSCs before and after 50 bending cycles. The OSCs using the GO/AgNW electrode showed a small change in efficiency of below 3%. As with the previous bending test results, the GO/AgNW electrode maintained its electrical path even after many bending cycles due to its excellent mechanical stability, and the efficiency of the OSCs did not change appreciably.

## 4. Conclusion

AgNWs were used as an electrode material on flexible substrates to replace the conventional ITO electrode. A flexible PET substrate was slot-die coated with the AgNWs, and the AgNWs were spray-coated with GO over-coatings to produce a new transparent electrode with enhanced stability that showed excellent characteristics of 87% transmittance and  $18 \Omega^{-1}$  sheet resistance. The fabricated transparent electrode showed high long-term stability and improved durability due to introducing the GO OCL, which lowered the inherently high surface roughness of the AgNW transparent electrode that had previously created a problem when the AgNW transparent electrode was applied to the OSCs. Furthermore, the fabricated GO/AgNW electrode OSCs showed higher efficiency than the OSCs with the conventional ITO transparent electrode because it absorbed more light in the working layer, and the GO/AgNW OSCs exhibited  $J_{sc}$  values of  $9.17 \pm 0.41 \text{ mA cm}^{-2}$  for P3HT:PC<sub>60</sub>BM and  $19.84 \pm 0.57 \text{ mA cm}^{-2}$  for PTB7:PC<sub>70</sub>BM. This resulted in enhanced PCEs of 3.32 and 7.66% due to the light transmittance characteristics of the GO/AgNW electrodes near 300–400 and 600 nm as well as the light scattering and trapping effects, even though the GO/AgNW transparent electrode had a sheet resistance higher by at least  $6 \Omega^{-1}$  and a transmittance lower by at least 3% than those of the ITO electrode. This improved light absorption correlated with the light transmittance and scattering, which was verified by measuring the haze factor and by a FDTD simulation. In addition to the improved device performance, the OSCs fabricated using the GO/AgNW electrodes showed a negligible change in efficiency (lower than 3%) after being subjected to 50 bending cycles. Furthermore, the developed GO/AgNW transparent electrode allows for devices with a large area, low cost, and high flexibility. Therefore, this electrode can be used to produce next generation flexible OSCs applicable to the outer walls of buildings and curved surfaces, which will cause great changes to the solar cell market. Moreover, due to their low surface roughness and excellent electrical and optical characteristics, the GO/AgNW electrodes are expected to be applicable to various flexible electronic devices, including low-cost OSCs, organic light-emitting diode (OLED), organic memory and organic transistor devices.<sup>41–43</sup>
