# Nanometer patterning of water by tetraanionic ferrocyanide stabilized in aqueous nanodrops†

Matthew J. DiTucci and Evan R. Williams\*

Formation of the small, highly charged tetraanion ferrocyanide,  $\text{Fe}(\text{CN})_6^{4-}$ , stabilized in aqueous nanodrops is reported. Ion–water interactions inside these nanodrops are probed using blackbody infrared radiative dissociation, infrared photodissociation (IRPD) spectroscopy, and molecular modeling in order to determine how water molecules stabilize this highly charged anion and the extent to which the tetraanion patterns the hydrogen-bonding network of water at long distance.  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{38}$  is the smallest cluster formed directly by nanoelectrospray ionization. Ejection of an electron from this ion to form  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_{38}$  occurs with low-energy activation, but loss of a water molecule is favored at higher energy indicating that water molecule loss is entropically favored over loss of an electron. The second solvation shell is almost complete at this cluster size indicating that nearly two solvent shells are required to stabilize this highly charged anion. The extent of solvation necessary to stabilize these clusters with respect to electron loss is substantially lower through ion pairing with either  $\text{H}^+$  or  $\text{K}^+$  ( $n = 17$  and  $18$ , respectively). IRPD spectra of  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  show the emergence of a free O–H water molecule stretch between  $n = 142$  and  $162$  indicating that this ion patterns the structure of water molecules within these nanodrops to a distance of at least  $\sim 1.05$  nm from the ion. These results provide new insights into how water stabilizes highly charged ions and demonstrate that highly charged anions can have a significant effect on the hydrogen-bonding network of water molecules well beyond the second and even third solvation shells.

## 1 Introduction

Multiply charged anions (MCAs) are ubiquitous in the condensed phases where they play important roles in the chemistry of materials and biology. Without stabilizing interactions with other molecules, such as solvents or counterions, small, highly charged anions can be unstable in isolation owing to strong coulombic repulsion between charges.<sup>1,2</sup> For example, the sulfate dianion constitutes 7.7% of dissolved inorganics in global seawaters and is found in many natural minerals, such as barite ( $\text{BaSO}_4$ ), celestine ( $\text{SrSO}_4$ ) and anglesite ( $\text{PbSO}_4$ ).<sup>3,4</sup> It plays an important role in the anaerobic respiration of sulfate-reducing bacteria, such as *Desulfovibrio gigas*, and in the atmospheric chemistry of aerosol radiative forcing, which has an impact on global climate changes.<sup>5,6</sup> Similarly, the phosphate trianion is stable in basic aqueous solutions and its dianionic conjugate acid acts as a buffer in eukaryotic cells.<sup>7</sup> However, isolated  $\text{SO}_4^{2-}$  and  $\text{PO}_4^{3-}$  are metastable and decay by electron

ejection with calculated lifetimes of  $1.6 \times 10^{-10}$  s and  $1.2 \times 10^{-14}$  s, respectively.<sup>8,9</sup>

The stabilities of MCAs within a given charge state generally increase with molecular size due to a greater separation between charges. Excess electrons in MCAs can be bound by a repulsive Coulomb barrier, which manifests as a result of the constructive potentials from short-range electron–nucleus attraction and long-range electron–electron repulsion.<sup>10–12</sup> For dicarboxylate dianions,  $^-\text{O}_2\text{C}(\text{CH}_2)_x\text{CO}_2^-$ , the electron affinity lessens with decreasing  $x$  due to an increase in the repulsive electron–electron potential.<sup>13</sup> The electron affinity is negative for  $x \leq 2$  ( $\sim 5.2$  Å). As a result, many large MCAs, such as fullerenes,<sup>14,15</sup> peptides,<sup>16</sup> proteins,<sup>17</sup> and DNA<sup>18,19</sup> are stable as isolated ions, whereas many small MCAs are not.

Small MCAs can be stabilized by interactions with solvent molecules.<sup>20</sup> High-valency anions in solvated clusters can be generated *via* electrospray ionization,<sup>20–22</sup> which provides a useful method for studying the role of solvation in the stabilities of MCAs as well as the distal extent of ion–water interactions. Wang and co-workers used photoelectron spectroscopy to investigate hydrated sulfate,  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$ , and oxalate,  $\text{C}_2\text{O}_4^{2-}(\text{H}_2\text{O})_n$ , clusters, which both require solvation by at least three water molecules to be thermodynamically stable.<sup>23,24</sup> Extrapolation of experimental data suggests  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$  with  $n = 1, 2$  are unstable by  $-0.9$  and  $-0.2$  eV,

† Electronic supplementary information (ESI) available: Complete citation for ref. 6, 43, 52 and 54, expanded region of nESI spectra in Fig. 1, comparison of individual radial distribution functions and atomic coordinates for the lowest energy  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$  structure along the molecular dynamics trajectory illustrated in Fig. 7. See DOI: 10.1039/c6sc03722d

respectively.<sup>20</sup> However, formation of  $\text{SO}_4^{2-}(\text{H}_2\text{O})_2$  *via* collisionally-induced dissociation from  $n = 4$  has been reported by Blades and Kebarle suggesting the cluster has a sufficient lifetime to be observed using mass spectrometry.<sup>25</sup>

The primary dissociative pathway for ion-containing clusters depends on the identity of the solvated ion, the cluster size and the internal energy of the cluster. For example, blackbody infrared radiative dissociation (BIRD) of  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$  at 21 °C with  $n \leq 5$  predominately results in charge separation to form  $\text{OH}^-(\text{H}_2\text{O})_k$  and  $\text{HSO}_4^-(\text{H}_2\text{O})_{n-k-1}$  product ions.<sup>26</sup> However, loss of a water molecule is entropically favored, and as a result,  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$  clusters with  $n < 5$  become dominant products under higher energy activation conditions. For this reason, a critical cluster size,  $n_c$ , has been defined as the size at which charge separation becomes energetically favored over the loss of a water molecule.<sup>27</sup> Recent results show hydrates of the ferricyanide trianion,  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_n$ , are unstable to electron ejection with a critical cluster size of  $n_c = 8$ , which IRPD spectroscopy and theory show is still within the first solvation shell of the ion.<sup>21</sup> Although isolated  $\text{P}_3\text{O}_9^{3-}$  and  $\text{Co}(\text{NO}_2)_6^{3-}$  have been reported previously,<sup>28</sup> subsequent experiments show  $n_c = 6$  is required to stabilize  $\text{P}_3\text{O}_9^{3-}$  with respect to charge separation and no evidence for isolated  $\text{Co}(\text{NO}_2)_6^{3-}$  was found under identical experimental conditions for forming  $\text{P}_3\text{O}_9^{3-}(\text{H}_2\text{O})_n$  and  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_n$ .<sup>21</sup> Therefore,  $\text{Fe}(\text{CN})_6^{3-}$  and  $\text{P}_3\text{O}_9^{3-}$  are the only small, high-charge density trianions that have been observed in gas phase aqueous clusters and at minimum require first-shell hydration for thermodynamic stability.

The distance to which ion-induced solvent orientation can extend has been studied in solution using multiple techniques, including diffraction,<sup>29,30</sup> spectroscopy<sup>31–33</sup> and theory.<sup>34,35</sup> Although ion-induced structuring of water molecules within the coordination shell is unambiguous, there have been conflicting interpretations amongst these results as to whether ion–water interactions can extend beyond the first solvation shell. For example, recent dielectric relaxation studies on hydrated phosphates indicate interactions extend into a full second solvation shell.<sup>33</sup> Although previous neutron diffraction studies have revealed extended ion–water interactions,<sup>36</sup> experiments with hydrated phosphate salts show no evidence for ionic influences beyond direct coordination to the ion.<sup>30</sup> The dynamic nature of water molecules makes probing weak ion-induced structural effects beyond a rigid inner shell a challenging endeavor. Measurements of MCAs in aqueous solution contain contributions from several counterions, which complicates the ability to assign interactions between water molecules and a single ion. Furthermore, many condensed phase techniques rapidly lose sensitivity with decreasing concentration such that uncoordinated water molecules are scarce and long-distance orientation effects from a single ion cannot be inferred.

The structure of size-selected  $(\text{H}_2\text{O})_n$  aqueous clusters in the gas phase can be studied using vibrational spectroscopy in the O–H stretching region. Water molecules at the surface of neutral clusters are free to orient with non-bonded hydrogens facing away from the cluster, which has been observed experimentally by the unique absorption band at  $\sim 3700 \text{ cm}^{-1}$ .<sup>37,38</sup> Using IRPD spectroscopy of mass-selected, ion-containing water

clusters, orientation effects on water by a single solvated ion free of any counterion contributions can be measured.<sup>21,39,40</sup> The sensitivity of this technique is not limited by the ratio of water molecules to ions. As a result, ion–water interactions can be measured to a hypothetical infinite dilution. IRPD spectra for  $\text{SO}_4^{2-}$  and  $\text{Fe}(\text{CN})_6^{3-}$  show that the non-bonded O–H stretch is absent with droplet radii up to  $\sim 0.7$  and  $0.8 \text{ nm}$ , respectively, as a result of long-distance orientation effects by the MCAs.<sup>21,39</sup>

The tetraanion ferrocyanide,  $\text{Fe}(\text{CN})_6^{4-}$ , is stable in aqueous solution, where it is commonly used as a probe for monitoring intracellular redox events in living cells.<sup>41</sup> It is also a precursor to the pigment Prussian blue,  $\text{Fe}_4[\text{Fe}(\text{CN})_6]_3$ , which is used also as a medical treatment for internal radioactive  $\text{Cs}^+$  and  $\text{Tl}^+$  poisoning and is being considered for clean-up of chemically-polluted natural waters caused by nuclear contamination.<sup>42–44</sup> Experiments on this ion in water have revealed a distinct inner solvation shell around ferrocyanide, but no information has been reported about how this anion influences the structure of water beyond the first solvation shell.<sup>45–48</sup> The direct measurement of extended ion–water interactions by an individual tetraanionic species is not feasible in the condensed phase due to the low concentrations necessary for hydration shells to exist unperturbed by counterions. However, the stability afforded by aqueous gas phase clusters and the sensitivity of IRPD spectroscopy to the orientation of surface water molecules provide a well-suited method for studying this high charge density tetraanion.

Here, the dissociation pathways and ion–solvent interactions in hydrated clusters of  $\text{Fe}(\text{CN})_6^{4-}$  are investigated using BIRD, IRPD spectroscopy and molecular modeling. Remarkably,  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  with  $n = 41$  is required for thermodynamic stability, although metastable clusters as small as  $n = 37$ , which dissociate *via* electron ejection, are observed. These findings illustrate that stability to electron ejection is achieved only through solvation with a nearly complete second hydration shell and therefore provides a direct observation of long-distance interactions between the ion and solvent. The spectroscopic signatures in the O–H oscillator region show ion-induced patterning of the hydrogen-bonding network can extend beyond a nanometer distance from the ion, corresponding to the fourth solvation shell. In combination with ion–solvent interactions in lower valency anions, a minimum Coulomb potential required for orienting surface water molecules in clusters can be determined. This is the first report of a critical cluster size for a small hydrated tetraanion and is the smallest, highest charge density tetraanion that has been formed in the gas phase.

## 2 Experimental and computational methods

All experimental data were obtained using a home-built 7.0 T Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer based on an instrument described elsewhere,<sup>49</sup> which has been upgraded to incorporate a 7 T magnet. Hydrated ions are formed by nanoelectrospray ionization (nESI) of 10 mM aqueous solutions of potassium hexacyanoferrate(II) trihydrate

(Sigma Aldrich, St. Louis, MO) with purified water from a Milli-Q system (Millipore, Billerica, MA). Solutions are loaded into borosilicate capillaries with tips that have been pulled to an inner diameter of  $\sim 1 \mu\text{m}$ . A platinum wire in contact with the solution is held at a constant potential of  $\sim 700 \text{ V}$  with respect to a heated metal capillary at the entrance of the mass spectrometer. Ions are guided *via* electrostatic lenses through five stages of differential pumping into the ion cell, which is enclosed by a copper jacket that is temperature-controlled to  $133 \text{ K}$  by a flow of liquid nitrogen and is thermalized for at least  $8 \text{ h}$  prior to data acquisition.<sup>50</sup> A pulse of dry nitrogen gas is introduced to bring the pressure of the vacuum chamber containing the ion cell to  $\sim 2 \times 10^{-6} \text{ Torr}$ , which helps to both trap and thermalize the ions. After an  $\sim 8 \text{ s}$  pump down period following the pulse gas, the pressure in the chamber decreases to  $\sim 2 \times 10^{-9} \text{ Torr}$ . Precursor ions of interest are subsequently isolated using a notched stored waveform inverse Fourier transform excitation.

IRPD spectra between  $2800$  and  $3800 \text{ cm}^{-1}$  are measured with infrared photons from a tunable OPO/OPA system (Laser-Vision, Bellevue, WA) pumped by the  $1064 \text{ nm}$  fundamental of a Nd:YAG laser (Continuum Surelight I-10, Santa Clara, CA) operating at a  $10 \text{ Hz}$  repetition rate. Mass-selected precursor ions isolated in the ion cell are irradiated for between  $\sim 0.25$ – $1.0 \text{ s}$  in order to produce substantial, but not complete, dissociation of the isolated aqueous cluster. A first-order rate constant is obtained from the relative abundances of precursor and product ions after photodissociation. The IRPD rate constants from laser irradiation are corrected for frequency dependent variations in laser power as well as dissociation due to BIRD.<sup>51</sup>

Molecular dynamics trajectories were obtained using Desmond 3.1 (Schrodinger, Inc., Portland, OR). The isolated ferrocyanide complex was first optimized using Q-Chem 4.0 (ref. 52) (Q-Chem, Inc., Pittsburgh, PA) at the B3LYP/LACVP+\*\* level of theory. This optimization uses a confined electronic structure that does not permit electron ejection. Water molecules were added thereafter with the optimized ferrocyanide complex in the center to model  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$ . During the simulation, the Fe–C force constants were increased in order to avoid cyano ligand loss, which does not occur experimentally for nanodrops of this size, but has been observed previously in QM/MM simulations.<sup>48</sup> The ion was not confined to the center of the aqueous cluster during the dynamics trajectories. An initial geometry relaxation was performed followed by equilibration with a  $1 \text{ ns}$  stochastic dynamics trajectory at  $133 \text{ K}$  using the OPLS 2005 force field with  $1.0 \text{ fs}$  time steps. In order to increase the conformational space explored in these trajectories, a series of annealing cycles were used to generate low-energy conformers. The upper temperature was chosen such that evaporation does not occur and water molecules can readily exchange between hydration shells. Each cycle consists of  $200 \text{ ps}$  at  $195 \text{ K}$  followed by gradual linear cooling over  $300 \text{ ps}$  to  $135 \text{ K}$ . The system is then equilibrated at  $135 \text{ K}$  for  $1 \text{ ns}$  followed by an additional  $1 \text{ ns}$  trajectory, from which five structures are taken in regular intervals. A comparison of the radial distribution functions for individual structures along the simulation shows that the hydrogen-bonding network of  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$

is not static within the final  $1 \text{ ns}$  of an annealing cycle at  $133 \text{ K}$  (Fig. S1†). This procedure is repeated 20 times in order to generate 100 low-energy structures for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$ . The atomic coordinates from these structures are used to measure radial distribution functions, dipole orientations and estimate the ion-surface distance for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$ . The same procedure for simulated annealing molecular dynamics was also used to generate 100 low-energy structures for  $(\text{H}_2\text{O})_{165}$ , which are used to measure water molecule dipole orientations in neutral clusters.

## 3 Results and discussion

### 3.1 Hydrated ion formation

Several different hydrated ions are observed in the nESI mass spectra of  $10 \text{ mM}$  aqueous solutions of  $\text{K}_4\text{Fe}(\text{CN})_6$  (Fig. 1), including the tetraanion ferrocyanide,  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$ . The smallest ferrocyanide cluster produced under a range of instrumental conditions is  $n = 38$ , but clusters with  $n > 320$  can be readily formed by reducing voltages to source optics, decreasing the temperature of the entrance capillary, and by optimizing the excitation waveform to enhance detection of larger clusters. Expanded regions of the mass spectra tuned for both small and large cluster sizes show the onset of ferrocyanide clusters at  $n = 38$  and the presence of protonated and potassiated adducts (Fig. S2†). Three isolated species without hydrate distributions are observed,  $\text{Fe}(\text{CN})_5^{2-}$  ( $m/z = 92.9$ ),  $\text{Fe}(\text{CN})_4^{2-}$  ( $m/z = 79.9$ ) and  $\text{Fe}(\text{CN})_3^{-}$  ( $m/z = 133.9$ ), which are formed *via* sequential ligand loss from the ferricyanide dianion.<sup>21</sup> A summary of all hydrated species formed by nESI is given in Table 1 and the isolated distributions of each hydrated ion are shown in Fig. 2.

The smallest  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  cluster formed by nESI is  $n = 38$ , whereas the largest  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_n$  is  $n = 40$ . Similarly, the smallest  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_n$  cluster is  $n = 8$  and the largest

Fig. 1 Nano-electrospray ionization mass spectra obtained from  $10 \text{ mM}$  aqueous solutions of  $\text{K}_4\text{Fe}(\text{CN})_6$  with instrumental conditions tuned for small (black) and large clusters (green). Magic number clusters for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  are observed at  $n = 46$  and  $64$ . Bare species with no hydrates include  $\text{Fe}(\text{CN})_4^{2-}$  (†) and  $\text{Fe}(\text{CN})_3^{-}$  (‡).

Table 1 Hydrated species formed by nESI of 10 mM  $K_4Fe(CN)_6$ 

Species formula	Smallest $n$	Largest $n$
$Fe(CN)_6^{4-}(H_2O)_n$	38	>320
$Fe(CN)_6^{3-}(H_2O)_n$	8	40
$Fe(CN)_6^{2-}(H_2O)_n$	0	7
$H_2Fe(CN)_6^{2-}(H_2O)_n$	0	>150
$HFe(CN)_6^{3-}(H_2O)_n$	17	>240
$HFe(CN)_6^{2-}(H_2O)_n$	0	17
$K_2Fe(CN)_6^{2-}(H_2O)_n$	0	>150
$KFe(CN)_6^{3-}(H_2O)_n$	18	>240
$KFe(CN)_6^{2-}(H_2O)_n$	0	19

Fig. 2 Hydrated ion distributions in nano-electrospray ionization mass spectrum obtained from 10 mM aqueous solution of  $K_4Fe(CN)_6$  with instrumental conditions tuned for small clusters. The most abundant ions are obtained from the mass spectral data and are plotted separately. Peaks from overlapping clusters are not included in these isolated spectra and account for gaps in the distributions for  $Fe(CN)_6^{4-}$  and  $HFe(CN)_6^{3-}$ .

$Fe(CN)_6^{2-}(H_2O)_n$  is  $n = 7$ . This is consistent with the previous results for  $Fe(CN)_6^{3-}(H_2O)_n$ , which show that electron ejection occurs for  $n \leq 8$ .<sup>21</sup> The absence of dianionic  $Fe(CN)_6^{2-}(H_2O)_n$  clusters with  $n > 8$  indicates this species is not present in solution, but is instead formed *via* gas phase dissociation of  $Fe(CN)_6^{3-}(H_2O)_n$  with  $n \geq 8$ . Similarly, the  $Fe(CN)_6^{3-}(H_2O)_n$  distribution from  $n = 8-40$  likely originates *via* electron ejection from larger unstable tetraanion ferrocyanide clusters. There is a similar correlation between charge states for the adducted species. Based on the distributions, electron ejection likely occurs from  $HFe(CN)_6^{3-}(H_2O)_n$  near  $n \approx 17$  and for  $KFe(CN)_6^{3-}(H_2O)_n$  with  $n \approx 19$ . The cluster size distributions indicate that the lower charge state species are formed in evaporating electrospray droplets through dissociative pathways and are not abundant in aqueous solutions of  $K_4Fe(CN)_6$ ,

which primarily contain the ferrocyanide tetraanion and trianionic ion pairs formed by protonation and potassiation of  $Fe(CN)_6^{4-}$ .

The smallest cluster sizes formed by nESI are smaller for  $HFe(CN)_6^{3-}$  ( $n = 17$ ) and  $KFe(CN)_6^{3-}$  ( $n = 18$ ) ion-paired species than  $Fe(CN)_6^{4-}$ . The greater stability associated with proton adduction compared to potassium ion adduction is likely due to more favorable interactions with the higher charge density of  $H^+$  with respect to  $K^+$ . These clusters are larger than the smallest clusters of  $Fe(CN)_6^{3-}$  ( $n = 8$ ), which indicates that the ferrocyanide trianion is intrinsically more stable than the trianions resulting from cation adduction to  $Fe(CN)_6^{4-}$ . Similarly, we see electron ejection from  $HFe(CN)_6^{3-}$  and  $KFe(CN)_6^{3-}$  results in dianionic species that are stable as bare ions as a result of the stability gained through ion-pairing. Therefore, the stability gained by cation adduction decreases the onset of dissociation and the critical cluster size for MCAs.

There are two magic number clusters for ferrocyanide at  $n = 46$  and  $64$ . Although peak overlap occurs for  $Fe(CN)_6^{4-}$  with  $HFe(CN)_6^{3-}$  and  $H_2Fe(CN)_6^{2-}$  (Fig. S2†), which are isobaric to within 0.01 and 0.03  $m/z$  for specific cluster sizes, these magic number clusters are confirmed to originate from the tetraanion based on the isotope spacing. Although the structural origin of the magic number cluster stabilities is unknown, infrared photodissociation studies have suggested that complex clathrate structures may form for clusters of this size, which optimize hydrogen bonding and ultimately lead to enhanced stability.<sup>21,53,54</sup>

### 3.2 Critical cluster size and dissociation pathways

The smallest  $Fe(CN)_6^{4-}(H_2O)_n$  cluster that is formed directly by nESI using a variety of source conditions is  $n = 38$ . In order to determine the dissociation pathways for this cluster, the isolated precursor  $Fe(CN)_6^{4-}(H_2O)_{41}$  (Fig. 3a) was dissociated using BIRD at 133 K (Fig. 3b-e). This cluster size was chosen in order to both maximize signal abundance and to avoid signal overlap caused by the clusters containing  $HFe(CN)_6^{3-}$  and  $H_2Fe(CN)_6^{2-}$  (Fig. S2†). Dissociation from  $Fe(CN)_6^{4-}(H_2O)_{41}$  occurs exclusively through loss of a single water molecule (reaction (1)):

After 0.5 seconds (Fig. 3b), a low abundance peak corresponding to  $Fe(CN)_6^{3-}(H_2O)_{40}$  is observed. This product cannot come directly from  $Fe(CN)_6^{4-}(H_2O)_{41}$  by direct loss of  $H_2O^-$  because the electron affinity of a single water molecule is negative. Therefore, this product is formed *via* electron ejection from  $Fe(CN)_6^{4-}(H_2O)_{40}$  (reaction (2)):

After 1.5 seconds (Fig. 3c),  $Fe(CN)_6^{3-}(H_2O)_{39}$ , which can be formed either through loss of a water molecule from  $Fe(CN)_6^{3-}(H_2O)_{40}$  or electron ejection from  $Fe(CN)_6^{4-}(H_2O)_{39}$ , starts to appear.  $Fe(CN)_6^{4-}(H_2O)_{40}$  also dissociates *via* water loss to form  $Fe(CN)_6^{4-}(H_2O)_{39}$ . Thus,  $Fe(CN)_6^{4-}(H_2O)_{40}$  dissociates

Fig. 3 Blackbody infrared dissociation spectra of (a)  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{41}$  showing product ions after (b) 0.5 s, (c) 1.5 s, (d) 2.0 s, (e) 7.5 s. Frequency noise is labeled with an asterisk (\*).

*via* two pathways – either through loss of a single water molecule (reaction (1)) or electron ejection (reaction (2)).

The abundance of  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_{40}$  is less than that of  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_{39}$  after 2.0 s (Fig. 3d). This inversion occurs as a result of only a single precursor dissociating to the former whereas the latter is produced by two dissociative pathways.  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_{38}$  begins to appear at 2.0 s and it can also be formed by two precursors. The smallest tetraanion observed from BIRD,  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{38}$ , appears after 7.5 s (Fig. 3e) and it exclusively dissociates *via* electron ejection. Therefore, the trianion clusters  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_n$  with  $n \leq 37$  are only formed by sequential water loss from the electron ejection products under low energy ambient blackbody radiation conditions.

The droplet radius for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{41}$  is  $\sim 0.67$  nm, which suggests that valence electrons must delocalize beyond the inner solvation shell for thermodynamic stability. Added stability from a subsequent shell can be due to either the added dielectric shielding by the solvent or an extended delocalization of the electron density into the second solvation shell. Evidence for the latter has been reported for the microsolvated fluoride anion,  $\text{F}^-(\text{H}_2\text{O})_6$ .<sup>55</sup> Calculations by Canuto *et al.* indicate that the six valence electrons of fluoride are distributed over the entire cluster. Dyson orbitals corresponding to  $\text{F}^-(\text{H}_2\text{O})_6$  vertical electron detachment energies (VEDE) suggest that the majority of the valence orbital density is delocalized over the water molecules with a maximum of 45% localized on fluorine, which occurs only for a high-energy VEDE.<sup>55</sup> Therefore, it is possible that delocalization of the orbital density for valence

electrons in  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  is required to extend beyond the coordinating hydration shell before the system is stable to electron ejection, which can explain the necessity of  $n \geq 41$  water molecules required in order to fully stabilize  $\text{Fe}(\text{CN})_6^{4-}$ .

Although  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_8$  exclusively dissociates *via* electron ejection under low energy BIRD conditions, water loss to form the  $n = 7$  cluster is entropically favored and becomes the major product under higher energy excitation conditions.<sup>21</sup> To investigate whether the same is true for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$ , infrared photons from a tunable laser at  $3521 \text{ cm}^{-1}$ , corresponding to the hydrogen-bonded region, were used to dissociate  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{41}$  for various times (Fig. 4). Sequential water molecule loss to form  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{38}$ , the smallest tetraanion observed using BIRD, is visible after only 0.25 s (Fig. 4a). Electron ejection products,  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_n$ , are also observed for  $n = 35$ –40. There is no evidence for electron ejection from  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{41}$ , which continues to dissociate exclusively through water loss with higher energy dissociation. After 0.55 s (Fig. 4b) water loss from  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{38}$  occurs to form  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{37}$ , which is the smallest tetraanion observed in these experiments. Longer dissociation times up to 1.00 s (Fig. 4c) result only in further sequential water loss from  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_n$ . Therefore, water loss is entropically-favored for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{38}$  and it occurs only under higher energy excitation conditions.

### 3.3 Patterning of water at long distances by $\text{Fe}(\text{CN})_6^{4-}$

To investigate the effect  $\text{Fe}(\text{CN})_6^{4-}$  has on the structure of the hydrogen-bonding network of water molecules located remotely from the ion, IRPD spectra of  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  at select sizes between  $n = 102$ –218 were measured (Fig. 5). There is a broad feature in the spectral region between  $\sim 3000$ – $3600 \text{ cm}^{-1}$  that is

Fig. 4 Infrared photodissociation spectra of  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{41}$  at  $3521 \text{ cm}^{-1}$  showing product ions after (a) 0.25 s, (b) 0.55 s, (c) 1.00 s. Frequency noise is labeled with an asterisk (\*).

observed for all cluster sizes. Intensity within this frequency range corresponds to water molecules that donate two hydrogen bonds either to the solvated ion or to adjacent water molecules. These oscillators include three- or four-coordinate water molecules in the bulk of the cluster that accept one (ADD, or acceptor–donor–donor) or two (AADD, or acceptor–acceptor–donor–donor) hydrogen bonds, or two-coordinate water molecules at the surface of the cluster that do not accept any hydrogen bonds (DD, or donor–donor). The maximum of this feature in the bonded O–H region for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  red shifts from  $3438\text{ cm}^{-1}$  ( $n = 102$ ) to  $3389\text{ cm}^{-1}$  ( $n = 218$ ), which is indicative of more optimal, stronger hydrogen bonding between water molecules in the larger clusters.

For hydrated clusters with  $n = 102$  and  $142$ , intensity in the region between  $3600$ – $3800\text{ cm}^{-1}$  is fully attributable to the tail of the fully hydrogen-bonded feature. A band near  $\sim 3700\text{ cm}^{-1}$  is due to water molecules that donate only one hydrogen bond, leaving the second O–H oscillator, commonly referred to as a “free O–H”, at the surface facing outward and away from the cluster. Absence of unique spectral features near  $\sim 3700\text{ cm}^{-1}$  indicates that all water molecules on the surface of the cluster are donating two hydrogen bonds. The spectra for clusters with  $n \geq 162$  have a feature centered at  $\sim 3704\text{ cm}^{-1}$  characteristic of three-coordinate AAD (acceptor–acceptor–donor) water molecules.<sup>53,54,56–60</sup> The frequency of these oscillators depends on the charge state of the hydrated ion, the extent of hydration and to a lesser extent, the size of the ion.<sup>61,62</sup> The intensity of this band increases for  $n = 182$  and  $218$ , indicating that the surface of

these clusters is populated with an increasing number of AAD water molecules.

For cations, the AAD oscillators are observable at the onset of hydration and increase in intensity for larger clusters, whereas for higher valency anions, this stretch is absent until there are a sufficient number of water molecules to effectively shield the ionic potential from water molecules at the cluster surface. The effect of the ion on the hydrogen-bonding network of water molecules in these clusters depends both on the orientation of water molecules directly coordinated to the ion and the electrostatic interaction of the solvated ion with the water dipole, which orients inwards toward the ion for anionic hydrated clusters. As a result, the initial presence of this free O–H stretch for an anionic cluster size indicates the extent of water patterning by the solvated ion. Although a free O–H stretch may appear for select microsolvated cluster sizes as a consequence of the available bonding motifs, *i.e.*, water molecules in a small cluster with no hydrogen-bonding partner accessible, there are no consistent free O–H stretches in the IRPD spectra of  $(\text{H}_2\text{O})_n^-$  until  $n \geq 15$ ,<sup>63</sup> for  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$  until  $n > 43$ ,<sup>39</sup> and for  $\text{Fe}(\text{CN})_6^{3-}(\text{H}_2\text{O})_n$  until  $n \geq 70$ .<sup>21</sup> While the exact location of the electron in  $(\text{H}_2\text{O})_n$  has not yet been resolved, it is evident that all water molecule hydrogen atoms interact with the diffuse electron cloud until  $n \geq 15$ .<sup>63</sup> In contrast, the higher charge state anions are expected to be located closer to the center of the cluster to maximize the stabilizing effects of solvation.

In order to ascertain the relationship between ionic charge state and patterning distance, the radii of clusters for which AAD water molecules begin to appear as a function of the anionic charge state is shown in Fig. 6. The four anionic charge states follow a linear trend with distance. This is the behavior expected from a Coulombic potential,  $V_{\text{Coulomb}}$ , produced by a point charge,  $Q$  (eqn (3)):

$$r = \frac{Q}{4\pi\epsilon V_{\text{Coulomb}}} \quad (3)$$

Fig. 5 Infrared photodissociation spectra of  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  with  $n$  between 102 and 218. The spectra have been expanded by  $5\times$  above  $3650\text{ cm}^{-1}$  in order to more clearly show the free O–H region, where acceptor–acceptor–donor (AAD) water molecules begin to appear for  $n = 162$  at  $3704\text{ cm}^{-1}$ .

Fig. 6 Linear relationship between the nanodrop radius for the onset of acceptor–acceptor–donor (AAD) water molecules at the cluster surface and corresponding anionic charge state.<sup>21,39,63</sup> The cluster radius is obtained from the water density assuming the nanodrops are spherical. Void space due to the ion is neglected.

where  $r$  is the radius of the hydrated cluster and  $\epsilon$  is the permittivity of water. Because  $r$  is proportional to  $Q$ , the potential,  $V_{\text{Coulomb}}$ , is expected to be roughly constant across the four anionic charge states for the cluster size where AAD water molecules appear. Using the permittivity of ice extrapolated to 133 K, this potential is calculated to be  $(2.4 \pm 0.6) \times 10^{-13} \text{ J C}^{-1}$ . This is the minimum potential required in order to orient the water molecules inward and prevent the emergence of free O-H oscillators at the cluster surface.

In order to obtain an estimate for the radius of these clusters and the number of hydration shells, a molecular dynamics trajectory was performed for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$ . A radial distribution function (Fig. 7a) shows three full solvation shells with the onset of a fourth shell. The first shell, centered  $\sim 0.38 \text{ nm}$  away from the ion, is the narrowest in width as a result of the strong interaction between water molecules and  $\text{Fe}(\text{CN})_6^{4-}$ . The width of subsequent shells expands as the water molecules interact less strongly with the central ion and have more rotational and translational freedom in comparison to the rotationally constricted inner water molecules. Each of the shells are  $\sim 0.25 \text{ nm}$  away from one another, with the third shell at  $\sim 0.87 \text{ nm}$  the widest. The fourth shell is centered at  $\sim 1.1 \text{ nm}$ , where the first water molecules with the characteristic AAD orientation reside.

A model of  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$  at the end of the trajectory (Fig. 7b) provides a cross sectional view of the hydration shells with overlaid colors based on the radial distribution function. The distance from the center of the ion to the surface of the cluster for several structures along the trajectory results in a radius of  $0.96 \pm 0.05 \text{ nm}$ , which is close to the distance obtained from a sphere using the density of bulk water ( $1.05 \text{ nm}$ ). The orientation of water molecules with respect to the solvated ion is shown in Fig. 8a. Water molecules within the first hydration shell interact strongly with the ion and have  $\langle \theta \rangle \approx 20^\circ$ . An increase in  $\langle \theta \rangle$  occurs until approximately  $0.7 \text{ nm}$ , which corresponds to the beginning of the third solvation shell. Although the average angle still faces inward toward the ion, water molecules in the second and third shells can

Fig. 7 (a) Radial distribution plot illustrating the structure for solvation shells around  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$ . Water molecules are counted within a bin width for a radial thickness of  $0.01 \text{ nm}$ . (b) Structure of  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$  taken at the end of a simulated annealing molecular dynamics trajectory. Colors are overlaid according to the edges of the corresponding solvent shell divisions provided in (a).

Fig. 8 Average angle  $\theta$  (depicted in insets) for water molecule orientation as a function of distance relative to (a) the solvated ion center in  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$  and (b) the geometric center of  $(\text{H}_2\text{O})_{165}$ . The horizontal dotted line corresponds to a water molecule orientation with the dipole perpendicular to the ion,  $\langle \theta \rangle = 90^\circ$ . Water molecules are counted within a bin width for a radial thickness of  $0.015 \text{ nm}$ . The gray box in (b) extends to  $0.28 \text{ nm}$ , which represents the average O–O distance between water molecules and therefore is not indicative of any propagating trends.

hydrogen bond with a four-coordinate AADD motif, which enthalpically stabilizes a wider range of orientations than are possible within the first hydration shell. A value of  $\langle \theta \rangle \approx 65^\circ$  persists into the third shell until water molecules are  $1.0\text{--}1.4 \text{ nm}$  away from the ion. These are the outer shell surface water molecules, which are restricted in orientation due to diminished hydrogen-bonding partners. Although this is the distance where free O–H water molecules begin to emerge, the average water molecule is clearly orienting inward as far as  $1.4 \text{ nm}$  from the ion with a value of  $\langle \theta \rangle \approx 55^\circ$ , which is more acute with respect to the third shell as a result of surface constraints.

For comparison, data was also obtained for  $\langle \theta \rangle$  with respect to the center of a neutral nanodrop. The void space of  $\text{Fe}(\text{CN})_6^{4-}$  in  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$  is  $\approx 5$  water molecules. Therefore,  $n = 165$  was chosen in order to model a neutral nanodrop of comparable size (Fig. 8b). Water molecules are randomly oriented ( $\langle \theta \rangle \approx 90^\circ$ ) up to  $\sim 0.9 \text{ nm}$ , where  $\langle \theta \rangle$  reaches a minimum of  $\sim 85^\circ$ . The water molecules between  $\sim 1.0\text{--}1.24 \text{ nm}$  are biased to face outward with respect to the center of the droplet, which is indicative of AAD water molecules that have a free O–H at the surface. The slight inward-facing bias between  $\sim 0.7\text{--}0.95 \text{ nm}$  is likely due to a restriction in orientation for water molecules in this shell in order to support the outward-facing motif of the surface water molecules. The furthest ion-oxygen distance reported for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{160}$  ( $d = 1.37 \text{ nm}$ ) is slightly larger

than that measured for  $(\text{H}_2\text{O})_{165}$  ( $d = 1.24$  nm) as a result of  $\text{Fe}(\text{CN})_6^{4-}$  not being confined to the nanodroplet center.

## 4 Conclusions

Aqueous clusters of  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  with  $n \geq 38$  can be formed using nESI. Ferrocyanide is the highest charge density tetra-anion that has been observed in the gas phase and measurements of aqueous nanodrops containing this anion provide a direct means for investigating how water stabilizes highly charged anions.  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{38}$  is the smallest cluster size observed directly by nESI and it dissociates exclusively by electron ejection under low-energy BIRD conditions. In addition to electron ejection, clusters of size  $n \geq 39$  can also dissociate by sequential loss of water molecules, which is the only dissociative pathway for clusters with  $n \geq 41$ . Higher-energy dissociation conditions obtained through IRPD result in the entropically-favored loss of a water molecule to form  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{37}$ , which is the smallest ferrocyanide cluster observed in these experiments.

The droplet radius for  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_{40}$ , the largest cluster unstable to electron ejection, is  $\sim 0.66$  nm. This corresponds to a nearly complete second hydration shell and is almost twice the radius observed for the trianion ferricyanide, which undergoes electron ejection with  $n \leq 8$  ( $r \approx 0.38$  nm).<sup>21</sup> This is a clear illustration of ion–water interactions that extend beyond the inner coordination sphere. The necessity of solvation with  $n \geq 41$  is likely due to delocalization of the orbital density for valence electrons in  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$ , which must extend into a nearly complete second solvation shell. Stability obtained through ion–ion interactions results in a high propensity for ferrocyanide to form ion pairs with  $\text{H}^+$  and  $\text{K}^+$ , which decrease the minimum solvation required for stability to electron ejection.

A free OH band in the IRPD spectrum of  $\text{Fe}(\text{CN})_6^{4-}(\text{H}_2\text{O})_n$  appears between  $n = 142$  and 162, indicating the ion–water interactions extend well beyond the second solvation shell. Remarkably, orientation of surface water molecules by the ion persists until  $n \geq 162$ , which is significantly larger than that observed for the ferricyanide trianion ( $n \geq 70$ ). Based on structures from molecular modeling, clusters of size  $n = 160$  have an average radius of  $\sim 0.96 \pm 0.05$  nm, which extends into a fourth solvation shell. There is a linear trend between anionic charge state and cluster radii for the onset of AAD water molecules. Based on the single value for the Coulombic potential at the cluster surface obtained from these results, a small pentanionic species is predicted to orient water molecules up to clusters of size  $n \approx 310$ , which have a radius of 1.3 nm.

The clusters in these experiments are equilibrated to cold temperatures (133 K) and the thermal motion of water molecules increases with temperature. At elevated temperatures, the entropic drive for surface water molecules to orient with free hydrogens will eventually predominate enthalpically favored hydrogen-bonding interactions. However, the perturbed water orientation observed up to nanometer length in these clusters is representative of interactions that, although diminished, will persist at warmer temperatures. These interactions are

especially important in environments where water is scarce, such as in living cells and reverse micelles, and will manifest as changes to the dynamics of surrounding water molecules as well as freezing point depression.<sup>40</sup> Long-distance forces originating from ions may also partially account for Hofmeister and other ion-related phenomena.
