Heterospin biradicals provide insight into molecular conductance and rectification†

Martin L. Kirk,^a David A. Shultz,^{*b} Jinyuan Zhang,^b Ranjana Dangi,^a Laura Ingersol,^a Jing Yang,^a Nathaniel S. Finney,^c Roger D. Sommer^b and Lukasz Wojtas^d

The correlation of electron transfer with molecular conductance (g : electron transport through single molecules) by Nitzan and others has contributed to a fundamental understanding of single-molecule electronic materials. When an unsymmetric, dipolar molecule spans two electrodes, the possibility exists for different conductance values at equal, but opposite electrode biases. In the device configuration, these molecules serve as rectifiers of the current and the efficiency of the device is given by the rectification ratio ($RR = g_{\text{forward}}/g_{\text{reverse}}$). Experimental determination of the RR is challenging since the orientation of the rectifying molecule with respect to the electrodes and with respect to the electrode bias direction is difficult to establish. Thus, while two different values of g can be measured and a RR calculated, one cannot easily assign each conductance value as being aligned with or opposed to the molecular dipole, and calculations are often required to resolve the uncertainty. Herein, we describe the properties of two isomeric, triplet ground state biradical molecules that serve as constant-bias analogs of single-molecule electronic devices. Through established theoretical relationships between g and electronic coupling, H^2 , and between H^2 and magnetic exchange coupling, J ($g \propto H^2 \propto J$), we use the ratio of experimental J -values for our two isomers to calculate a RR for an unsymmetric bridge molecule with known geometry relative to the two radical fragments of the molecule and at a spectroscopically-defined potential bias. Our experimental results are compared with device transport calculations.

Introduction

Over 40 years ago, Aviram and Ratner¹ proposed a design strategy for a unimolecular organic rectifier that employed aromatic π -system donor (D) and acceptor (A) moieties connected to one another by the σ -orbitals of a saturated bridge (B) fragment. To date, true molecular rectification² has been difficult to achieve^{3,4} with molecular rectification ratios (RRs), defined as the ratio of the electrical current propagated through the molecular junction in the forward and reverse bias directions, rarely exceeding 10.^{4–7} Although the D–B–A rectifier concept allows for remarkable design and control of the active rectifying component, a critical problem remains regarding the nature of the D–B–A coupling with metallic electrodes. Namely,

the contact geometry of the molecule sandwiched between the metallic electrodes is generally unknown. This requires the construction of conductance histograms consisting of thousands of individual measurements⁸ in order to assess the conductance properties of single molecules. In these experiments, it is difficult to assess the productive geometry(ies) of the molecule relative to the electrodes and, for rectifying molecules, the geometry responsible for the preferred current direction. The geometric relationship between a rectifying molecule and the conductance under forward and reverse bias is generally assessed with quantum chemical computations that provide transmission probabilities using a precise device geometry.

In the present work, we remove these ambiguities entirely by replacing the metallic electrodes with molecular electrode equivalents. These electrode equivalents are spin-bearing organic radicals poised at spectroscopically defined chemical potentials, *vide infra*, which are covalently attached to the D–A rectifying fragment. As shown in Fig. 1, semiquinone (SQ) and nitronyl nitroxide (NN) radicals⁹ serve as biased electrodes with covalent chemical bonds as the contacts. The pyridine–thiophene/thiophene–pyridine (P–T/T–P) bridges serve as the molecule spanning the electrodes of a break-junction device and the two constitutional isomers **SQ–P–T–NN** and **SQ–T–P–NN** model the effect of reversing the bias direction. The large bridge dipole moment ($\mu_{\text{calc}} = 1.94$ D, see ESI†) satisfies one of the

Fig. 1 Bond-line drawings and thermal ellipsoid plots (left and right) for SQ-T-P-NN and SQ-P-T-NN with corresponding single-molecule rectifier devices (center). Here, SQ and NN serve as analogs of biased electrodes. Different bridge-radical torsion angles model aspects associated with unsymmetrical anchor group attachment, while electron-deficient pyridine bound to electron-rich thiophene bridge fragments ensure unsymmetrical orbital alignment with electrodes. Bond torsions between bridge T–P π -systems serve to partially decouple bridge fragments.

requirements for unimolecular rectification as previously proposed by Aviram and Ratner.¹ Intrinsic unimolecular rectification, where the energy levels of the molecule shift as a function of the applied bias direction, is of interest since this is an inherent property of the molecule. Herein, we evaluate the results of single-molecule electron transport calculations, which have found broad utility in the molecular electronics community, with experimental observables derived from electronic absorption, magnetic susceptibility, and molecular electronic structure computations on structurally well-defined small molecule analogs of molecular break-junction and STM devices.

Experimental

Synthesis and characterization

Molecules have been synthesized and characterized according to established procedures that have been published in the literature.^{10–19} Synthetic methods, characterization, and X-ray crystallographic material is given in the ESI.†

Transport calculations

Transport calculations were performed using ATK 2016.0 v16.0.^{20–22} The device configuration consists of the left Au electrode, the molecular bridge (scattering region), and the right Au electrode. Both the left and right gold electrodes consist of nine layers with each layer comprised of a 3×3 array of Au(111) atoms, for a total of 81 gold atoms per electrode. For the electrodes, the C or z direction is periodic in the system. This is also the direction of electron transport. Initial geometry optimizations of the T–P molecular bridge were performed using Gaussian 09²³ with 6-31g(d',p') basis set and a B3LYP functional. Electrode surfaces were constructed by cleaving the bulk crystal, and using a copy of this to form the second electrode. The T–P

molecule was then placed on the surface of the left electrode and subsequently connected to the right electrode through terminal sulfur atoms to create the final device geometry. Prior to creating the final device geometry, the bulk configuration was optimized using a single-zeta basis set for the gold atoms (to save computational time) and a double zeta basis set for all other atoms. The optimization was performed using ATK-DFT with a Perdew Zunger local density approximation (LDA-PZ) exchange correlation. After this bulk optimization, the configuration was converted into a final device geometry for all subsequent calculations. The $5 \times 5 \times 51$ K -point sampling has been used in x , y , z -directions, respectively.

The boundary conditions were Dirichlet (fixed boundary condition) in the z direction, which is the direction of transport. The boundary conditions in the x and y directions were disabled so they could not be changed but the default parameterization is periodic for the x and y directions. The NEGF formalism was used to calculate the non-equilibrium electron density of the central region of the device.

The Landauer–Büttiker formula²⁴ relates transmission probabilities to conductance, g ($g = I/V$). This formula is used to calculate the voltage dependent current, $I(V)$, across a molecular junction, which is determined by integrating the transmission function, $T(E, V)$, according to eqn (1).

$$I(V) = \frac{e}{h} \sum_{\sigma} \int T_{\sigma}(E) \left[f \left(\frac{E - \mu_R}{k_B T_R} \right) - f \left(\frac{E - \mu_L}{k_B T_L} \right) \right] dE \quad (1)$$

Here, e is the charge of the electron, h is Planck's constant, eV_{bias} is the bias window equivalent to $\mu_R - \mu_L$ (with $V_{\text{bias}} = V_L - V_R$), $T_{\sigma}(E)$ is the aforementioned transmission coefficient for the spin component, σ , that describes the junction at an energy E and at a given bias voltage, V_{bias} . The Fermi-Dirac distribution

functions are given by $f(E - \mu_R)/k_B T_R$ and $f(E - \mu_L)/k_B T_L$ and the right and left electrodes, respectively, with associated chemical potentials of μ_R for the right electrode and μ_L for the left electrode. All electron transport properties were computed using the ATK software package that includes virtual nanolab associated analysis modules. We have used the MPSH technique^{4,25} to understand the molecular orbital origin of the resonant peaks in the transmission spectra. The transmission eigenstates have been directly compared to the associated molecular orbitals of the isolated T-P molecule to understand the molecular orbital origin of a given transmission peak, including how the transmission peaks are modified with the application of an external bias across the left and right electrodes.

Results and discussion

We use torsionally-rotated D (thiophene) and A (pyridine) fragments connected by a σ -bond to partially decouple the D and A bridge fragments, in analogy with Aviram and Ratner's use of a cycloalkane bridge. We recently evaluated both σ - and torsionally restricted π contributions to electronic coupling at parity of D and A and showed that the σ contribution to the electronic coupling is ~ 13 times weaker than a planar, conjugated π -contribution,¹⁹ in agreement with theoretical predictions.^{26,27} Given that H_{DA}^2 is proportional to the molecular conductance (g), it can be anticipated that there will be an ~ 200 fold decrease in the transport mediated by the σ -system relative to a π -bridge at parity of bridge distance. Thus, although σ bonds may be used to effectively create tunnelling barriers between D and A, this effect will occur at the expense of attenuated conductance in both forward and reverse bias directions, and will limit the utility of the rectifier.

Molecular design, structure, couplings and rectification ratios

Biradical ligand complexes **SQ-P-T-NN** and **SQ-T-P-NN** have been synthesized by standard procedures (see ESI for synthetic details†) used for the preparation of other SQ-B-NN biradical molecules.^{10–14,16,17,19,28–30} Bond line drawings and X-ray structures for **SQ-P-T-NN** and **SQ-T-P-NN** are given in Fig. 1 along with relevant SQ-B, B-B, and B-NN torsion angles. While the SQ to NN distances are within 0.1 Å, the torsion angles are quite different. For **SQ-T-P-NN**, the torsion angles are 15°, 26° and 36° for the SQ-T, T-P and P-NN torsion angles, respectively. The corresponding torsion angles for **SQ-P-T-NN** are 16°, 12° and 11°.

Since both the SQ and NN are $S = 1/2$ spin-bearing units, the relative magnitudes of the bridge-mediated SQ-NN electronic coupling ($H_{SQ-B-NN}$) in **SQ-P-T-NN** and **SQ-T-P-NN** can be conveniently determined at high resolution by measuring the relative magnitudes of their respective bridge-mediated SQ-NN magnetic exchange interactions, $J_{SQ-B-NN}$.^{13,14,31–34} This can be accomplished using temperature- or magnetic field-dependent spectroscopies (e.g., electronic absorption spectroscopy^{14,35} or EPR,³⁶) or magnetic susceptibility measurements with the singlet-triplet exchange splitting being equal to $2J_{SQ-B-NN}$ according to the Heisenberg exchange Hamiltonian, eqn (2):

$$\mathcal{H}_{SQ-B-NN} = -2J_{SQ-B-NN}\hat{S}_1 \cdot \hat{S}_2 \quad (2)$$

where the \hat{S}_i are the spin operators for the $S = 1/2$ radical spins.

Magnetic susceptibility data, plotted as $\chi_{para} \cdot T$ products vs. temperature are displayed in Fig. 2A and B (see ESI for additional magnetic data†). Fits (derived from eqn (2)) to the data give $J_{SQ-TP-NN} = +51.2 \pm 0.6 \text{ cm}^{-1}$ and $J_{SQ-PT-NN} = +56.5 \pm 0.5 \text{ cm}^{-1}$.

In terms of molecular design principles, it is desirable to explicitly relate the magnetic exchange, J_{SQ-NN} , to the total, SQ-B, and B-NN electronic couplings (H_{SQ-NN} , H_{SQ-B} , and H_{B-NN} , respectively) and the molecular conductance (g) according to the relationship described by eqn (3) based on theories developed by Anderson,³⁷ McConnell,³⁸ and by Nitzan.³⁹

$$\sqrt{J_{SQ-B-NN}} \propto H_{SQ-B-NN} = \frac{H_{SQ-B} \cdot H_{B-NN}}{\Delta} \left(\frac{H_{BB}}{\Delta} \right) \cong c\sqrt{g} \quad (3)$$

Thus, magnetic exchange is proportional to conductance ($J \propto g$; where c is a proportionality constant), and eqn (3) is the electronic coupling theory complement to models for molecular rectification in terms of the experimental observables for the SQ-B-NN biradical complexes **SQ-P-T-NN** and **SQ-T-P-NN**, the SQ \rightarrow B-A charge transfer energy, Δ ; and the biradical magnetic exchange coupling, $J_{SQ-B-NN}$. Here, the relative magnitudes of electronic couplings H_{SQ-B} and H_{B-NN} (as well as the SQ \rightarrow B-NN charge transfer energy, *vide infra*) describe how strongly the unsymmetrical SQ and NN π -systems (which serve as biased electrode equivalents) interact with those of the unsymmetric bridge fragment. The magnitude of H_{BB} quantifies the degree of coupling between the π systems of the unsymmetric, n bridge fragments.³⁸

Electronic absorption spectra for the two isomeric biradicals are shown in Fig. 2C. The spectra are characterized by absorption bands of the constituent chromophores (SQ $\sim 840 \text{ nm}$ and NN $\sim 580 \text{ nm}$), and an intense intraligand charge transfer (ILCT) band at $\sim 475 \text{ nm}$. TD-DFT calculations and analogy with other SQ-B-NN species allows assignment of the ILCT band in **SQ-P-T-NN** and **SQ-T-P-NN** as possessing dominant SQ(SOMO) \rightarrow B-NN(LUMO) character with a minor contribution from the B-NN(HOMO) \rightarrow SQ(SOMO) one-electron promotion (Fig. S3†). The ILCT transition is important, since the excited state configurations involved directly contribute to the magnitude of the observed ground state ferromagnetic exchange by configurational mixing with the ground state. This configurational mixing has been quantified in the context of a valence bond configuration interaction (VBCI) model, which has been successfully used to evaluate the electronic structure of SQ-B-NN heterospin biradical complexes.^{13,14} The ILCT band energy can be used to approximate Δ in eqn (3) and (4), where Δ also represents the intrinsic molecular bias between SQ and NN.^{15,17} Given the small $\sim 900 \text{ cm}^{-1}$ energy difference in the two ILCT band maxima, we can make the approximation that $\Delta_{SQPTNN} \cong \Delta_{SQTPNN}$.

With $\Delta_{SQPTNN} \cong \Delta_{SQTPNN} \equiv \Delta$ and the J -values for the two constitutional isomers, eqn (3) relates the exchange coupling to the conductance. Thus eqn (3) can be recast in terms of ratios with $J_{SQ-TP-NN}/J_{SQ-PT-NN}$ equating to an effective RR, g_{TP}/g_{PT} , using this unsymmetric bridge, eqn (4):

$$\frac{J_{\text{SQTPNN}}}{J_{\text{SQPTNN}}} = \frac{51.2 \text{ cm}^{-1}}{56.5 \text{ cm}^{-1}} = \frac{g_{\text{TP}}}{g_{\text{PT}}} = 0.91 \equiv \text{RR} \quad (4)$$

The effects of molecular conformation can be accounted for by modifying eqn (3) with the $\cos \phi$ values determined by X-ray heterospin biradical complexes. These bond torsions control the degree to which the π -orbitals of nearest neighbor fragments become decoupled by torsional rotation. In addition to the decoupling between fragments, the torsional rotations affect the degree of unsymmetric orbital alignment between the bridge and the SQ/NN electrode equivalents. Thus, the magnitude of $J_{\text{SQ-TP-NN}}/J_{\text{SQ-PT-NN}}$, and the associated RRs, can be modulated by changes in the torsion angles between nearest neighbors ($\phi_{\text{SQ-P}}$, $\phi_{\text{SQ-T}}$, $\phi_{\text{T-P}}$, $\phi_{\text{P-NN}}$ and $\phi_{\text{T-NN}}$, Fig. 1) as shown in eqn (5):

$$\sqrt{J_{\text{SQBNN}}} \propto H_{\text{SQB-NN}} = \frac{\cos \phi_{\text{SQB}} H_{\text{SQB}} \cdot \cos \phi_{\text{BNN}} H_{\text{BNN}}}{\Delta} \times \left(\frac{\cos \phi_{\text{BB}} H_{\text{BB}}}{\Delta} \right) \cong c\sqrt{g} \quad (5)$$

Recently, we demonstrated that $H_{\text{SQ-B-NN}} (\sim \sqrt{J_{\text{SQ-B-NN}}}$, eqn (3)) varies smoothly as products of cosines of the SQ-B and B-NN torsion angles.¹⁹ This product (including $\cos \phi_{\text{BB}}$) is 0.70 for **SQ-T-P-NN**, while for the **SQ-P-T-NN** isomer, the product of cosines is 0.93. Substituting these $\cos \phi$ products into eqn (5), gives eqn (6a) and (b). Squaring eqn (6a) and (6b) and taking the ratio gives eqn (7).

$$\sqrt{J_{\text{SQTPNN}}} \propto H_{\text{SQTPNN}} = 0.70 \frac{H_{\text{SQTP}} \cdot H_{\text{TPNN}}}{\Delta} \left(\frac{H_{\text{TP}}}{\Delta} \right) \cong c\sqrt{g_{\text{TP}}} \quad (6a)$$

$$\sqrt{J_{\text{SQPTNN}}} \propto H_{\text{SQPTNN}} = 0.93 \times \frac{H_{\text{SQPT}} \cdot H_{\text{PTNN}}}{\Delta} \left(\frac{H_{\text{PT}}}{\Delta} \right) \cong c\sqrt{g_{\text{PT}}} \quad (6b)$$

$$\begin{aligned} \frac{J_{\text{SQTPNN}}^0}{J_{\text{SQPTNN}}^0} &= \frac{J_{\text{SQTPNN}}}{J_{\text{SQPTNN}}} \times \frac{0.93^2}{0.70^2} = \frac{51.2 \text{ cm}^{-1}}{0.49} \times \frac{104 \text{ cm}^{-1}}{56.5 \text{ cm}^{-1}} = \frac{g_{\text{TP}}^0}{g_{\text{PT}}^0} \\ &= 1.58 \equiv \text{RR}^0 \end{aligned} \quad (7)$$

Thus, when the bridge molecule is planar (all $\cos \phi_{ij} = 1$) and at parity of the individual H_{ij} and $\text{SQ} \rightarrow \text{B-NN}$ charge transfer energies (Δ) we expect the intrinsic RR^0 for planar T-P to be 1.58 times greater than that of planar P-T, $\frac{g_{\text{TP}}^0}{g_{\text{PT}}^0} = 1.58$. Clearly, this value indicates a switch in the preferred direction of conductance compared to the “experimental” value, since the experimental $J_{\text{SQ-TP-NN}}/J_{\text{SQ-PT-NN}}$ ratio is 0.91, corresponding to a $g_{\text{TP}}/g_{\text{PT}}$ RR of 0.91. The 0.70 and 0.93 rotational prefactors in eqn (6a) and (6b) suggest that greater intrinsic coupling is achieved in planar **SQ-T-P-NN** compared to **SQ-P-T-NN** ($\sim +104$ and $+66 \text{ cm}^{-1}$, respectively, eqn (7)) allowing for a greater (and inverted) RR^0 .

Superexchange/orbital pathway for coupling and the mechanism for rectification in T-P bridges

Within the context of our VBCI model, the topology of the T-P bridge HOMO and LUMO can be used to explain why the **SQ-T-P-NN** and **SQ-P-T-NN** magnetic exchange interactions and ILCT transitions are so similar, and provide a rationale for why the T-P unsymmetric bridge may be ineffective at promoting large RRs. Despite strong D-A character in the T-P bridge, both the bridge HOMO and LUMO that are responsible for the ILCT energy/intensity, magnetic superexchange coupling, and electronic transport are highly symmetric (Fig. 3).

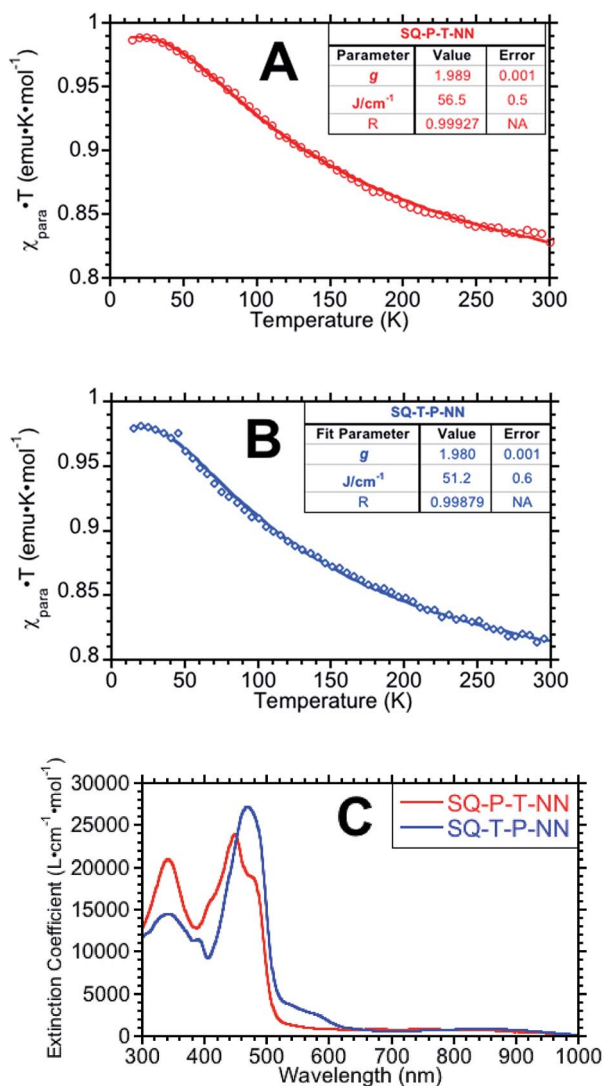

Fig. 2 $\chi_{\text{para}} \cdot T$ vs. temperature plots for **SQ-P-T-NN** (A) and **SQ-T-P-NN** (B). (C) Electronic absorption spectra for **SQ-T-P-NN** and **SQ-P-T-NN**. $\text{SQ} \rightarrow \text{B-NN}$ ILCT bands appear $\sim 475 \text{ nm}$ and closely approximates Δ in eqn (3), (5), (6a) and (6b).

Consequently, the magnitude of the P–T bridge torsion angle is insufficient to reduce the π -coupling in the D–A bridge. Thus, a critical component of an unsymmetric bridge necessary for unimolecular rectification is lost, highlighting the importance of understanding conductance orbital topology and excited state electronic structure contributions to molecular rectification. The intrabridge bond torsion effectively serves as an analog of the σ tunnelling barrier as was originally proposed by Aviram and Ratner.¹ Maximum bridge localization occurs when the P and T bridge components are oriented perpendicular to each other. Although this would result in the elimination of π -coupling between the T–P bridge components and simulate a tunnel junction, this decoupling occurs with a marked reduction in conductance under both forward and reverse bias. This effect has been keenly illustrated and quantitated by our recent studies on bond torsion modulation of electronic coupling in an SQ-[(CH₃)_nphenylene]-NN series.¹⁹ Thus, a key component to increased rectification while maintaining a relatively high degree of conductance along a single bias direction resides in increasing the magnitude of the intrabridge T–P torsion just enough to partially decouple and localize the donor (thiophene) and acceptor (pyridine) components of the bridge fragment.

Computational assessment of molecular electron transport mediated by T–P

Our electronic absorption, magnetic susceptibility, and electronic structure calculations show that the electronic coupling matrix element that couples the T–P bridge to the SQ and NN radical electrode equivalents must be very similar for both SQ–P–T–NN and SQ–T–P–NN. Furthermore, this electronic coupling is

primarily mediated by the T–P bridge LUMO and HOMO wavefunctions.

Here, we employ a computational approach utilizing an electrode-molecule-electrode (two-probe Au electrode) construct to compute molecular electron transport properties of the unsymmetric dipolar T–P molecule under forward and reverse bias directions in a device setup. Our primary goal here is to evaluate the results of electron transport calculations in the context of experimentally determined SQ–P–T–NN and SQ–T–P–NN electronic and geometric structure, since bridge-mediated magnetic exchange couplings are related to conductance through the electronic coupling matrix element.³⁹ The results of our transport calculations on Au_(L)–S–T–P–S–Au_(R) constructs with the T–P molecule bond torsion, ϕ_{T-P} , equal to 20° (\approx the average of the T–P torsion angles in the biradicals determined from X-ray crystallography, see Fig. 1) are displayed in Fig. 4. The current (I) vs. bias potential (V) curve (I – V curve) in Fig. 4A shows that the computed bias dependent RRs are small. This is to be expected due to the small ϕ_{T-P} torsion angle and the concomitant high degree of delocalization in the bridge HOMO and LUMO wavefunctions, and fully in line with our experimentally determined exchange coupling ratios using SQ and NN radicals as biased molecular electrode analogs. The effective bias between SQ and NN in our SQ–P–T–NN and SQ–T–P–NN biradicals can be approximated by the energy (~ 2.6 eV) of the SQ(SOMO) \rightarrow B–NN(LUMO) ILCT band in Fig. 2C ($= \Delta$ in eqn (3)). We determine a RR = 1.24 at ± 2.56 V in the I – V curve of Fig. 4A. This can be directly compared to our experimental results for SQ–P–T–NN and SQ–T–P–NN, where we observe a magnetic exchange determined RR⁰ of 1.58, a value that is in remarkably good agreement with the RR computed for the unsymmetrical T–P bridge in the device configuration using Au electrodes. This further illustrates the utility of using unsymmetrical bridge fragments to relate the results of transport calculations and experimental magnetic exchange coupling constants at geometric parity of the bridge contact geometry. Furthermore, the direct comparison of ratioed current values at a fixed bias potential (*i.e.* RRs) with $J_{SQ-TP-NN}/J_{SQ-PT-NN}$ values eliminates complications associated with an unknown proportionality constant (c , eqn (3)) that relates the two measurable quantities; magnetic exchange couplings and current.

Further analysis of this system can be obtained by understanding the electronic origins of the transmission in the context of a tight-binding model.^{40,41} Under this approximation, the transmission function, $T(E, V)$, can be cast as eqn (8).

$$T(E, V) = \frac{4\pi^2 \gamma_L^2(V) \text{DOS}_L(E, V) \gamma_R^2(V) \text{DOS}_R(E, V)}{[E - E(V)]^2 + \pi^2 [\gamma_L^2(V) \text{DOS}_L(E, V) + \gamma_R^2(V) \text{DOS}_R(E, V)]^2} \quad (8)$$

Here, the electrode density of states is given by $\text{DOS}_{L,R}(V)$, the molecule-electrode coupling parameters for the left and right contacts are $\gamma_L(V)$ and $\gamma_R(V)$, and the $E(V)$ are the molecular energy levels that are affected by the Stark effect under forward or reverse bias. We note that $\text{DOS}_{L,R}(V)$, $\gamma_L(V)$ and $\gamma_R(V)$, and $E(V)$ are all voltage dependent parameters that contribute to the

Fig. 3 VBCI model for SQ–P–T–NN illustrating bridge HOMO and LUMO mirror plane-like symmetry: nearly identical p-orbital coefficients on T and P rings at the atoms of attachment to NN and SQ radicals renders the T–P bridge ineffective at both exchange coupling and rectification. Red, green and blue arrows indicate dominant one-electron contributions to the intraligand CT band. The blue and red transitions probe dominant CT contributions to magnetic superexchange pathways. Insets: DFT computed T–P LUMO and NN HOMO wave functions (see ESI†) that mix with frontier NN orbitals.

Fig. 4 Results of transport calculations for the T-P bridge fragment under forward and reverse bias. (A) The I - V curve. Dashed, vertical lines indicate the intrinsic bias of SQ-PT-NN and SQ-TP-NN = Δ ($2C$, eqn (3)). (B) Bias-dependent transmission spectrum (note that the bias window is shown in blue). Transmission spectra correspond to the applied bias voltages in A, with -4 V at the bottom and $+4$ V at the top of the plot. The rectification ratio at ± 2.56 V is observed to be $RR = 1.3$. A plot of RR vs. bias is shown in Fig. S3.†

current through the transmission function. Since our focus here is on intrinsic unimolecular rectification, we have used Au for both the left and right electrodes, and identical thiol anchoring groups to these electrodes. Thus, the dominant contributions to differences in the transmission function under forward and reverse bias are primarily determined by the bias dependent energy levels of the T-P molecule sandwiched between the two Au electrodes.

Fig. 4B displays the computed transmission as a function of bias voltage. At small applied voltages, $|V| \leq 1.0$ V, a single transmission peak is found in the bias window. The dominant molecular orbital contribution to the transmission is obtained by evaluating the molecular projected self-consistent Hamiltonian (MPSH) states associated with a given transmission peak.

These MPSH states are the S-T-P-S molecular orbitals that are modified through bonding to the Au electrodes. The MPSH state that contributes to the -0.32 V transmission eigenstate is the MPSH HOMO (78%), which is virtually identical to the free T-P molecular HOMO. At applied potentials lower than -1.5 V, another transmission peak begins to enter the bias window that is also dominantly MPSH HOMO in nature. Conversely, applied voltages greater than $+1.5$ V result in a transmission peak of different electronic origin beginning to enter into the bias window. The zero bias transmission peak at $+2.23$ V possesses dominant MPSH LUMO character that mirrors the LUMO of free T-P. Thus, both the T-P HOMO and LUMO contribute to conductance in the device geometry depicted in Fig. 5, with the T-P HOMO contributing prominently at low bias voltages due, presumably, to the known pinning effect of molecular HOMOs to the electrode Fermi level.^{4,42,43}

The T-P HOMO and LUMO molecular orbitals that are responsible for transmission are the same as those that contribute to the ground state magnetic exchange coupling in SQ-P-T-NN and SQ-T-P-NN. The thiol groups in the transmission calculations increases the degree to which the molecular eigenstates can couple with those of the Au electrodes. As such, bridge molecular orbitals that possess large S contributions in the bias window dominate the conductance. The same effect is true for the SQ-bridge-NN systems. Here the S atom contact analogs are the bridgehead carbons of the NN and SQ radicals. In a Hückel approximation, magnetic exchange is maximized when the bridge MOs admix with the bridgehead carbons, and

Fig. 5 Top: Zero-bias transmission eigenstates at -0.32 V and $+2.23$ V. Bottom: Molecular projected self-consistent Hamiltonian (MPSH) states indicating the effects of the molecular orbitals under the influence of their interaction with the electrode surfaces. We note that the MPSH HOMO and LUMO correspond to the HOMO and LUMO of the free T-P molecule. These two orbitals are involved in the two dominant one-electron promotion contributions that constitute the observed intraligand charge transfer band in SQ-P-T-NN and SQ-T-P-NN. And the magnetic exchange interaction *via* the VBCI model.

magnetic exchange is minimized for bridge MOs that do not possess NN and SQ bridgehead carbon character.

Interestingly, the T-P(LUMO) MPSH state enters the bias window at potentials near the energy of the SQ(SOMO) \rightarrow B-NN(LUMO) ILCT band. The T-P bridge HOMO plays a dominant role in conduction at low bias voltages, but it plays a minor role in magnetic exchange coupling ($\sim 14\%$ contribution to the ILCT transition). The relative importance of a highly delocalized HOMO orbital for molecular conduction is increased when the MPSH HOMO is pinned to the electrode Fermi level in the device construct.⁴ Thus, a key difference in bridge-mediated electronic communication emerges as a result of using molecular electrode equivalents as opposed to metallic electrodes. While the T-P(HOMO) is pinned to the electrode Fermi level in the device construct and contributes to conduction at low bias voltages, orbital contributions to enhanced electronic coupling using molecular contact analogs can be different. In **SQ-P-T-NN** and **SQ-T-P-NN** this effectively favors the B-NN(LUMO). This is due to different resonance interactions between the bridge molecular orbital energy levels and those of the SQ(SOMO) and the NN(LUMO). In general, using other molecular contact analogs that possess different reduction potentials and orbital topologies will further modulate the bridge mediated electronic coupling. Future device constructs may be able to make more extensive use of molecular electrodes in order to make more reliable contacts⁴⁴ and to enhance specific bridge orbitals for conductance and enhanced molecular rectification.

Conclusions

The biradical approach can be used to estimate RRs for nearly any bridge at any conformation observed in X-ray crystal structures and provide critical bridge electronic structure information from spectroscopy and magnetic measurements. Our work shows that the exchange coupling ratio is close to 1 for **SQ-P-T-NN** and **SQ-T-P-NN**. When understood in the context of transport calculations, small RRs are indeed expected for the P-T bridge in near planar conformations. This is exemplified by P-T bridge HOMO and LUMO mediated transmission in a near planar bridge geometry. Here, both the bridge HOMO and LUMO wavefunctions are observed to be highly symmetric with respect to a plane that bisects the SQ and NN fragments of the bridge, leading to contact invariance with respect to transmission through these orbitals. Despite the small degree of unsymmetric coupling promoted by the T-P bridge, increasing the intrabridge bond torsion should dramatically enhance RRs. Surprisingly, these results also show that bond torsions can potentially reverse the intrinsic RR through a given bridge fragment.

In addition, this approach provides an important link that connects transport calculations that determine conductance, and spectroscopic/magnetic data that determine magnetic exchange couplings to an effective electronic coupling matrix element. Further efforts at understanding the electronic structure origins of molecular conductance and rectification, as well as optimizing molecular rectification using this approach are currently underway.
