Large-scale fabrication of translucent and repairable superhydrophobic spray coatings with remarkable mechanical, chemical durability and UV resistance†

Danfeng Zhi,^a Yao Lu,^{ID} ^b Sanjayan Sathasivam,^b Ivan P. Parkin ^{ID} ^b and Xia Zhang ^{ID} ^{*ab}

In this work, we present a simple and effective silica–polymer-based spray coating to create a translucent, mechanically durable, chemically stable, healable and environmentally friendly superhydrophobic coating with UV resistance. The coatings retained superhydrophobicity after UV radiation for at least 175 hours, heating up to 150 °C, exposure to strong acids and bases, and various mechanical durability tests such as knife scraping, hand kneading, and multiple cycles of tape peeling 100 times. In addition, the coating treated sponge was used for continuous oil–water separation through connection with a vacuum system, the separation efficiency was greater than 95% for various liquid hydrocarbons. This substrate-independent spray coating is believed to be useful for large-scale application for both outdoor and indoor applications.

1. Introduction

Coating is an essential step in adjusting the surface properties of materials.¹ Lotus leaf-inspired superhydrophobic coatings have attracted much attention in recent years due to their various applications, such as self-cleaning,^{2,3} anti-fogging,⁴ delayed frosting,⁵ anti-corrosion,^{6,7} *etc.* However, poor durability, high fabrication costs, and difficulties in maintaining the air cushions have restricted large-scale applications of superhydrophobic surfaces.^{8–10} To expand the lifespan of superhydrophobicity, one approach is to get the monoliths of a material that possesses low surface-energy microstructures that extend throughout its entire volume. If the uppermost layer is damaged or removed upon scraping by abrasion, the newly exposed rough surface with low surface-energy is also water-repellent, thereby making the superhydrophobicity more stable.^{11,12} Another approach to improve the durability of superhydrophobicity is to endow the surface with a self-healing ability. When the surface loses superhydrophobicity, it can be healed by external stimulus, including pH, enzymes, heating, light irradiation, and redox activities.^{13,14} For example, Li *et al.*^{15,16} fabricated superhydrophobic coatings with preserved

self-healing agents of reacted fluoroalkylsilane (FAS) in the coatings, which were porous and ridged. Once the primary top FAS layer was decomposed, rendering the surface hydrophilic, the preserved healing agents could migrate to the coating surface in a humid environment to heal the superhydrophobicity of the coating.

Superhydrophobic organic–inorganic hybrid composite coatings have received much more attention because of the simultaneous advantages of both inorganic and organic materials.^{17,18} Using inorganic nanoparticles to create nano- or microscale structures on organic polymer coatings is a concept for fabrication of hybrid superhydrophobic nanocoatings.^{19,20} However, the inorganic nanoparticles have difficulty to cooperate with the organic polymer materials, which leads to phase separation during the curing process. To resolve this problem, surface functionalization is required to endow nanoparticles with hydrophobicity.¹⁶ Unfortunately, such hydrophobized nanoparticles rely on compounds that are either expensive or harmful to the environment (*e.g.*, perfluorooctanoic acid).¹¹ In consideration of the practical conditions, superhydrophobic coatings are expected to be applied both for outdoor and indoor applications. In terms of outdoor applications, for example, superhydrophobic surfaces could be used on transmission lines for anti-icing purposes.²¹ This requires a superhydrophobic coating that can be applied on a large scale with good mechanical robustness, UV resistance and stability to corrosive liquids such as acids and bases. In consideration of indoor applications, superhydrophobic surfaces are expected to be

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c7ta02488f

used for water proofing and self-cleaning purposes and even with some translucency as shower room glass.

One of the most important potential applications of superhydrophobic surfaces is for oil–water separation, which usually involves the use of a superhydrophobic–oleophilic mesh or membrane.^{22,23} However, the mesh/membrane systems can hardly be used for continuous oil–water separation, and may require some water/oil collection or disposal processes, which results in some energy and economic costs.^{24–27}

Here, we demonstrate a simple and effective spray process to create a translucent, mechanically durable, chemically stable, healable and environmentally friendly superhydrophobic coating with remarkable UV resistance. The spray was fabricated using functionalized SiO₂ nanoparticles and fluorine-free polymers, and can be easily treated on both hard (glass and copper) and soft substrates (cotton, textile and sponge). The coatings retained superhydrophobicity after intense UV radiation for at least 50 hours, heating up to 150 °C, exposure to strong acids and bases, and various mechanical durability tests such as knife scraping, hand kneading, and multiple cycles of tape peeling for at least 100 times. In addition, the coating treated sponge was used for continuous oil–water separation through connecting with a vacuum system, the separation efficiency was above 95% for various liquid hydrocarbons in water, including silicone oil, methylbenzene, trichloromethane, *n*-hexane, paraffin oil and dichloromethane.

2. Experimental section

2.1. Preparation of superhydrophobic silica powder

Sodium silicate was dissolved in 50 mL of deionized water to form a 0.15 mol L⁻¹ solution (defined as Solution A). Then 25 mL of 0.18 mol L⁻¹ hydrochloric acid (Solution B) was added dropwise into the stirred Solution A. After half of Solution B was added, 25 mL of 0.0125 mol L⁻¹ hexamethyldisilazane (HMDS) was added to Solution A together with the rest of Solution B dropwise. The suspension was heated to 60 °C and was stirred for 4 h. After cooling down to room temperature, the suspension was separated into two layers with a white foam layer floating on top. The foam was collected by filtration and washed repeatedly using a mixed solution of deionized water and ethanol until Cl⁻ could not be detected using silver nitrate solution by visual examination. The filtered cake was re-dispersed into a mixed solution of deionized water and ethanol at a volume ratio of 1 : 1 to form an emulsion. Finally, the emulsion was spray-dried and hydrophobic silica nanoparticles were obtained.

2.2. Preparation of superhydrophobic SiO₂/polyurethane (PU) coatings

The durable superhydrophobic SiO₂/PU coating was fabricated by a simple spray method. In the synthesis of the suspension, 0.8 g of hydrophobic silica nanoparticles, 1.7 g of the polyurethane pre-polymer and 0.17 g of 4,4'-methylene bis(2-chloro-benzenamine) as a curing agent were added into 15 g of acetone, and the mixture was magnetically stirred for 30 min

at room temperature to make a uniform suspension. The suspension was sprayed onto the substrates with a 2.5 M Pa compressed air gas using a spray-gun with a nozzle diameter of about 0.8 mm. The distance between the spray gun and the substrates was about 15 cm. The coatings were finally cured at 150 °C for 1 h. For soft materials such as paper, fabric, cotton and sponge, the substrates were initially ultrasonicated into the suspension for 3 min, and then cured at 150 °C for 1 h.

2.3. Preparation of silica/epoxy resin superhydrophobic coatings

1.8 g of epoxy resin, 0.54 g of the curing agent and 0.54 g of hydrophobic silica nanoparticles were dispersed in 15 g of acetone to make a uniform suspension. The suspension was sprayed onto the hard and soft substrates and then followed by a curing process. The conditions of spray coating and the curing processes are the same as those used in the silica/PU coating preparation.

2.4. Characterization

The surface morphology of the samples was examined with a field emission scanning electron microscope (FESEM, JSM-6701F). The surface components of the samples were analyzed with an X-ray photoelectron spectrometer (XPS, AXIS ULTRA). Thermogravimetric (TG) measurements were done with NETZSCH STA 449 C using a dynamic heating rate of 10 °C min⁻¹. The contact angles (CA) and sliding angles (SA) of water and other liquids (coffee, milk, vinegar, red wine, and cola) were measured using a DSA-100 optical contact-angle meter (Kruss Company, Ltd, Germany) at room temperature (22 °C). The average CA value was determined by measuring the same sample at five different positions. The volume of all liquids was 8–10 mL when the contact angles and sliding angles were measured. The image of the droplet was obtained with a digital camera (NIKON, P600). UV radiation (obtained from a 8 W Hg lamp with a wavelength of 254 nm) was used to test the UV resistance of the prepared coatings, and the water contact angles of the coatings were measured every 10 hours of UV radiation. The transparency of the coatings was tested using a UV-vis spectrometer (UV-1800PCS, Mapada Instruments). The transmittance of each sample was recorded at 340–800 nm and collected at ambient temperature.

2.5. Sandpaper abrasion test

The sandpaper abrasion tests were carried out on the SiO₂/PU coating as well as the purchased commercial NeverWet coating. In this test, the coating weighing 300 g was placed face-down on the sandpaper (standard glass paper, grit no. 600) and moved for 23 cm; the sample was rotated by 90° (face to the sandpaper) and then moved for 10 cm. This process is defined as one abrasion cycle, which guarantees the surface is abraded longitudinally and transversely in each cycle even if it is moved in a single direction.

2.6. Oil/water separation

The average absorption capacity was determined by measuring the same sample at least five times. After being rinsed thoroughly with alcohol and dried, the as-prepared sponges could be reused for oil/water separation for many cycles.

3. Results and discussion

3.1. Superhydrophobic silica/polymer composite coating

Silica nanoparticles were fabricated *via* a simple process.²⁸ Firstly, sodium silicate was hydrolyzed to form silicic acid under the acidic conditions. Condensation polymerization occurred through hydration among the hydroxyls of the silicic acids in three dimensions and the Si and O were bonded to each other to form nano-silica clusters. Large numbers of hydroxyls were left on the surface of the nano-clusters, while the HMDS was hydrolyzed to produce trimethylsilyl and ammonia. As the nano-clusters formed, the trimethylsilyl reacted rapidly with the hydroxyl of nano-silica to form a modified layer on the surface of the clusters. Here, the trimethylsilyls substituted a majority of the active groups of silica and result in steric hindrance, which prevented the silica nanoparticles from continuously growing or agglomerating. Thus, the hydrophilic silica nanoparticles were transformed into superhydrophobic ones and had excellent compatibility with the organic solution. As shown in 1a, the silica nanoparticles can be dispersed in organic media such as carbon tetrachloride, liquid paraffin, hexane, and acetone to form a colourless solution. Fig. 1a inset shows a photograph of the obtained silica powder. The silica nanoparticles were hydrophobic and could be absorbed on the liquid/air interface leading to the formation of liquid “marbles”, as shown in Video S1 in the ESI.† In the TEM image (Fig. 1b), the silica clusters composed of nanoparticles had diameters of several tens of nanometers. The XRD pattern of the sample shows that the obtained silica is X-ray amorphous as shown in

Fig. 1c. Fig. 1d shows the thermogravimetric analysis image of the silica nanoparticles, the weight loss was 3.4% at 200 °C due to the surface absorption. There is a strong decrease between 200 °C and 700 °C, which refers to the decomposition of the surface modification with a weight loss of 7.8%. Fig. 1e shows the optical images of glass coated with a SiO₂/PU coating with a thickness of about 7 μm (Fig. S1a in the ESI†), and all the letters show good readability under the coated glass. The transmittance spectrum of the coated glass in the visible region (300–800 nm) is a rational characterization of transparency as shown in Fig. 1f. Fig. 1g shows the optical images of glass coated with a 18 μm SiO₂/epoxy resin coating (Fig. S1b in ESI†), and the letters under the coating also show readability. The transmittance of the coated glass was about 70% as shown in Fig. 1h.

Table 1(a) and (b) show the water contact angle and sliding angle of different substrates treated with a SiO₂/PU and SiO₂/epoxy resin coating, respectively. It can be seen that all the contact angles were larger than 150° as well as the sliding angles that were lower than 10° on both hard substrates (glass and copper) and soft substrates (textile, paper, sponge, and cotton), indicating the excellent superhydrophobic performance.

Table 1 Water contact and sliding angles of a SiO₂/polymer coating on different substrates

Substrate	(a) SiO ₂ /PU		(b) SiO ₂ /epoxy resin	
	CA (°)	SA (°)	CA (°)	SA (°)
Glass	158.0 ± 1.5	1.52 ± 0.5	158.8 ± 1.5	1.55 ± 0.5
Copper	155.3 ± 1.5	1.66 ± 0.5	156.8 ± 1.5	1.56 ± 0.5
Cotton	153.8 ± 1.5	8.13 ± 0.5	151.9 ± 1.5	8.05 ± 0.5

(h) Transmittance spectrum of the glass slide before and after coating with SiO₂/epoxy.

Furthermore, the obtained coatings were shown to be highly repellent to a wide variety of liquids including coffee, milk, cola, red wine and vinegar (ESI Fig. S2†).

To understand the relationship between the mass fraction of SiO₂ nanoparticles and the surface wettability, we measured the water contact angles with different mass fractions of SiO₂ powder in PU and epoxy resin, respectively, as shown in Fig. S3.† When PU was used as the hydrophobic agent, the water contact angle increased as the mass fraction of SiO₂ powder increased. The water contact angle reached 150° when the mass fraction of SiO₂ was increased to 30 wt%, and it did not significantly change as the mass fraction of SiO₂ nanoparticles further increased. When epoxy resin was used as the hydrophobic agent, the water contact angle did not reach 150° until the mass fraction of SiO₂ nanoparticles was increased to 20 wt%, and it only increased slightly as the mass fraction of SiO₂ nanoparticles further increased.

Fig. 2 shows the SEM image of different substrates (hard and soft) before and after being treated with a SiO₂/polymer coating. The original substrate surfaces were smooth, but they show highly textured surface morphologies after the treatments with hydrophobic silica nanoparticles. Hydrophobic silica nanoparticle aggregations contributed to both the surface roughness and the reduction of the surface free energy, which are the main factors responsible for superhydrophobicity.²⁹ The inset is the photograph of the water droplet image and corresponding contact angle image, and it was found that after treatment with the coating, the soft and hard substrates became superhydrophobic with water contact angles larger than 150°. The thermal stability of the SiO₂/PU and SiO₂/epoxy resin coating was tested by thermogravimetric analysis as shown in Fig. 3a and b, respectively. As shown in Fig. 3a, there was no obvious weight loss before 200 °C; between 240 °C and 450 °C, it had a dramatic decrease, indicating the heat-induced decomposition

Fig. 2 Surface morphology of (a) original coating, (b) SiO₂/PU and (c) SiO₂/epoxy resin coating treated samples on various substrates.

Fig. 3 TG images of (a) SiO_2/PU and (b) $\text{SiO}_2/\text{epoxy resin}$ treated coatings.

of polyurethane with a 68% weight loss. Another strong decrease from 450 °C to 700 °C corresponded to further decomposition of polyurethane. Fig. 3b shows the TG image of

the $\text{SiO}_2/\text{epoxy resin}$. From 150 °C to 700 °C, the total loss was about 75% corresponding to the burning of the epoxy resin, and the rest was the inorganic SiO_2 component. Although the

(f) Water contact angles and sliding angles after multiple cycles of tape peeling tests.

coating decomposed at high temperature, both SiO₂/PU and SiO₂/epoxy resin coatings show significant heat resistance below 150 °C, further providing evidence that the superhydrophobic coatings are sufficient for daily use.

3.2. Mechanical durability and pH-tolerance

Durability is an important factor that affects the practical application of superhydrophobic materials, especially mechanical friction that leads to the damage of the surface micro/nano structure, resulting in the loss of the superhydrophobicity. In this work, we used different methods to evaluate the durability of the superhydrophobic coatings such as abrasion, compression, adhesive tape peel, and corrosive attack. As shown in Fig. 4a–d and Videos S2 and S3 in the ESI,[†] the coating on soft and hard substrates had good mechanical durability after induced damage such as knife scraping, folding, and kneading, and the coating still maintained its water-repellency. In large-scale practical applications, the adhesion between coatings and substrates is one of the most important issues that should be considered. Here, we used multiple cycles of tape peeling to investigate the adhesion between superhydrophobic coatings and the substrates as shown in Fig. 4e. Fig. 4f shows the water contact angles and sliding angles of the superhydrophobic SiO₂/PU sample after multiple cycles of tape peeling tests. The contact angles do not significantly change and remain above 150° after 100 peeling cycles. The sliding

angles increase with the peeling cycles, but remain below 10°, which suggests that the superhydrophobicity maintains a stable Cassie–Baxter state and that the coatings have strong adhesion to the substrate. Also, the coating has good mechanical durability, it was able to withstand at least 200 cycles of compression and release and maintained its superhydrophobicity unchanged (ESI Fig. S4[†]).

The sandpaper abrasion test was used to further examine the surface mechanical durability of our superhydrophobic coatings and compare it to those of the commercially available NeverWet superhydrophobic coating as shown in Fig. S5.[†] It was observed that the water contact angles of the SiO₂/PU coatings remained above 150° after 35 abrasion cycles, indicating that the superhydrophobicity was retained after mechanical abrasion. Under the same abrasion conditions, the water contact angle of the commercial coating reduced to less than 150° after only 20 abrasion cycles, indicating that its superhydrophobicity was lost. Therefore, our superhydrophobic coatings showed excellent abrasion resistance which is even better than that of the commercial products.

Long-term chemical durability is essential for superhydrophobic coatings to be used in practical applications especially in an outdoor environment. In this paper, we used corrosive liquids (acids and bases) to test the chemical durability of superhydrophobic coatings. Fig. 5 shows the water CA and sliding angle of the superhydrophobic coating as a function of continuous contact time with extremely corrosive liquids. It

Fig. 5 Contact angles and sliding angles as a function of contact time with (a) acidic and (b) alkaline liquids on SiO₂/PU coatings, and (c) acidic and (d) alkaline on SiO₂/epoxy resin surfaces.

was noticed that the water droplet became smaller with time due to the evaporation in air. As shown in Fig. 5a and b, the contact angles of the acidic (pH = 1) droplet and the alkaline (pH = 14) droplet remained larger than 150° after 50 min. Despite slight decreases in the contact angles with contact time, the sliding angles were still below 10°, indicating that the superhydrophobic SiO₂/PU coating retained its superhydrophobicity. This result is very important for the application of the silica/PU nanocomposite coating with sustainable superhydrophobicity in corrosive liquids. Fig. 5c and d show the chemical tests on superhydrophobic SiO₂/epoxy resin coatings upon contact with acidic (pH = 1) and alkaline (pH = 14) droplets. The contact angles decreased to 150° after contacting with the acidic droplet for 25 min and contacting with the alkaline droplet for 15 min, respectively. The coating lost its superhydrophobicity with further immersion, however, the water droplets could still roll off easily as the sliding angles were below 15°. The superhydrophobic SiO₂/PU coating has superior chemical durability compared with the superhydrophobic SiO₂/epoxy resin coating.

3.3. UV irradiation resistance and healability of superhydrophobicity

Another important concern is the UV resistance of superhydrophobic surfaces in consideration of outdoor applications.

Superhydrophobic composite coatings are usually subject to UV-light exposure, because the presence of large quantities of organic components leads to the oxidation and formation of hydrophilic groups.³⁰ Herein, the water contact angles did not significantly change under UV irradiation even after 175 hours of exposure as shown in Fig. S6 in ESI.† This is because SiO₂ is not photoactive, and both PU and epoxy resin agents are also stable upon UV exposure. Therefore, the SiO₂/PU and the SiO₂/epoxy resin coatings were UV resistant.

To test the healability of the superhydrophobic SiO₂/PU and SiO₂/epoxy resin coatings, we used ozone attack to degrade the surface superhydrophobicity. The coatings became hydrophilic after exposure to ozone for 15 min, with water contact angles of 30° for SiO₂/PU and 80° for SiO₂/epoxy resin coatings. Here, our superhydrophobic coatings could be easily healed after heating at 150 °C for 3 min. As shown in Fig. 6a, the water contact angles recovered to be greater than 150° after the healing process, and the hydrophilicity and superhydrophobicity of the coatings could be reversibly transformed for at least 8 cycles. XPS analysis was employed to investigate chemical composites that induced the switching from superhydrophobicity to hydrophilicity as shown in Fig. 6b, and there were three peaks corresponding to Si, C, N and O on the SiO₂/PU surfaces. After ozone irradiation for 15 min, the carbon content decreased from 19.2 wt% to 17.8 wt% and the O content increased from 50.6 wt% to

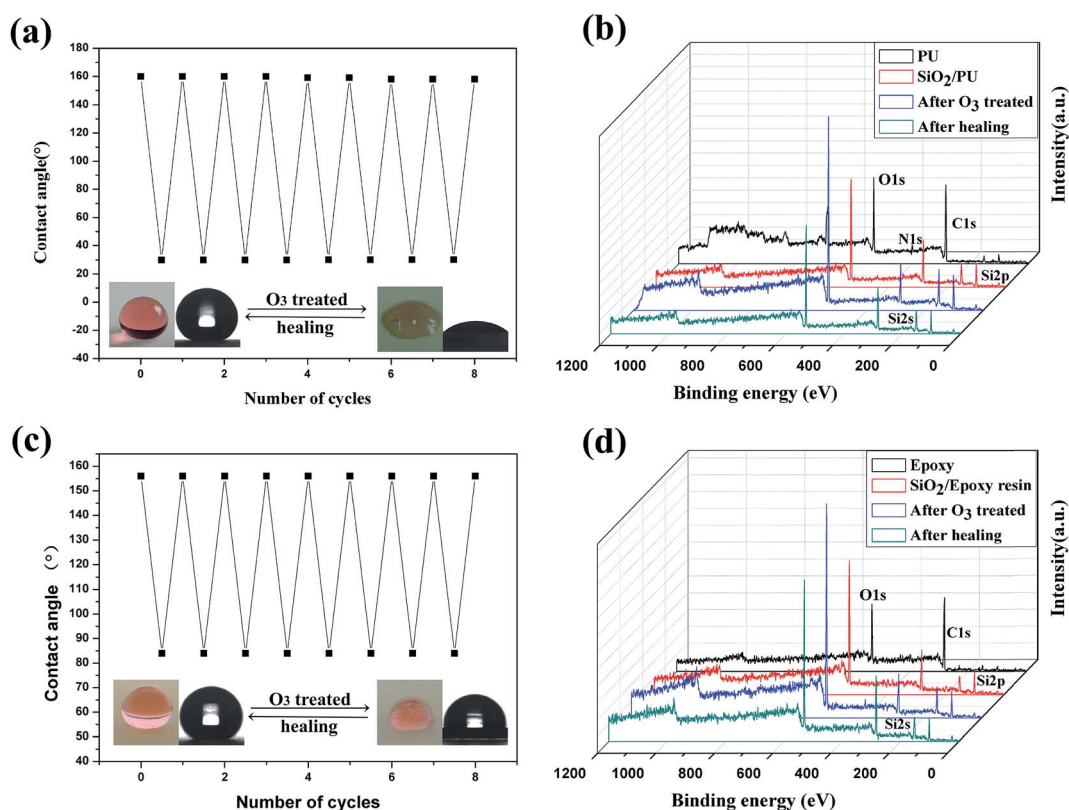

Fig. 6 Reversible superhydrophobic–hydrophilic transition of the as-prepared SiO₂/PU (a) and SiO₂/epoxy resin (c) under ozone irradiation and heat treatment. XPS analysis of SiO₂/PU coating (b) and SiO₂/epoxy resin (d) before and after ozone irradiation.

Fig. 7 Self-cleaning properties of SiO₂/PU in air (a–c) and contaminated by oil in air (d–f).

67.4%. After the healing process, the C content increased and reached 25.9 wt%, leading to the recovery of superhydrophobicity. Fig. 6c and d show the switching from superhydrophobicity to hydrophilicity after the ozone attack. In terms of the superhydrophobic SiO₂/epoxy resin coating, the variation of chemical composition was similar to that of SiO₂/PU (Table S1 in the ESI†). It is believed that the variation of the chemical composition accounts for the transformations in the surface wettability. When the coatings were exposed to the ozone attack,

large numbers of hydrophilic species including –OH groups were formed on the surface as ozone is a strong oxidizer. From Fig. 6 and Tables S1 and S2 in the ESI,† it can be seen that the O/C atomic ratio increased significantly after the ozone attack, indicating that the surface has been oxidized and more hydrophilic components increase. After being heated in the air, the coating recovered its water-repellency. From the XPS analysis, the O/C atomic ratio decreased significantly from 5 to 2.5, which shows that the hydrophobic carbon component increases. It is

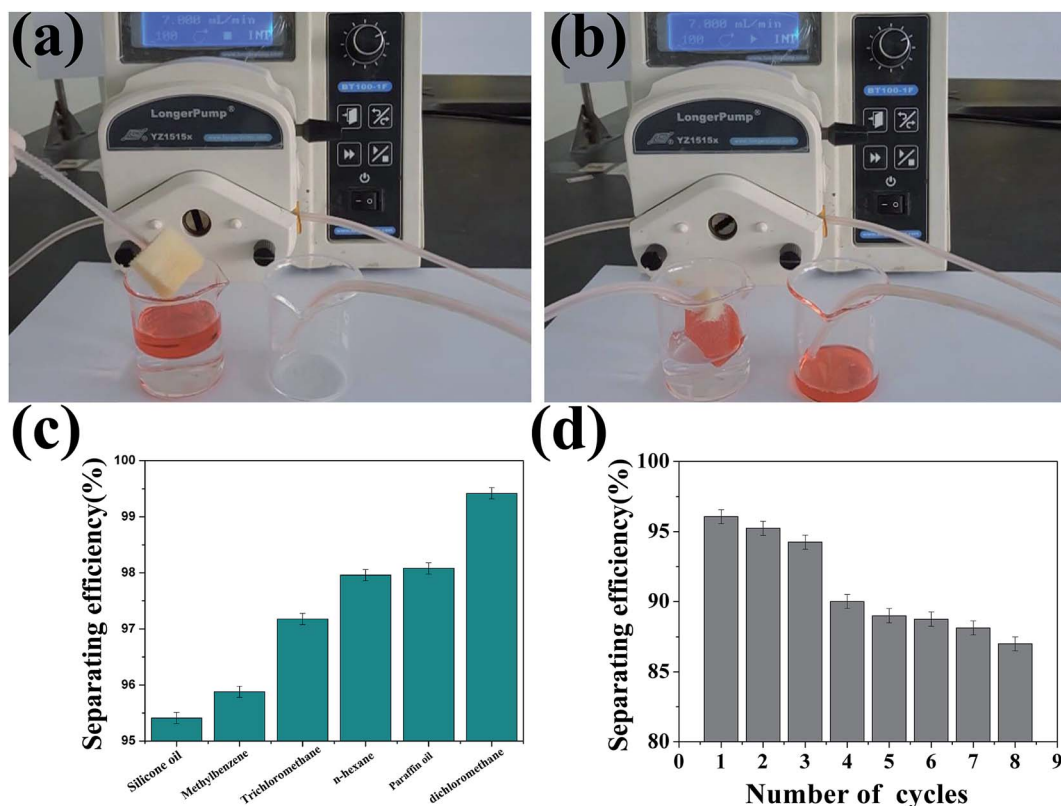

Fig. 8 (a and b) Photographs of the continuous absorption of silicone oil (dyed red) from water. (c) Oil/water separating efficiency. (d) Separating efficiency recyclability of the sponge.

believed that driven by the reduction of the high interfacial energy between the hydrophilic surface and hydrophobic air, the polar groups (–OH) were “pushed” into the bulk (*i.e.* the reorientation of polar groups) and the hydrophobic C–H chains diffused to the uppermost layer (*i.e.* the chain diffusion).^{31,32} Therefore, after being heated, the surface recovered its superhydrophobicity.

3.4. Self-cleaning properties

In nature, the Lotus leaf is an example of a self-cleaning surface. The rolling motion of water droplets on the leaf surface can pick up the dust and leave the superhydrophobic surface clean. Herein, the SiO₂/polymer coatings also show self-cleaning properties. As shown in Fig. 7a–c and Video S4,† water could easily take away the dust and leave the treated filter paper surface clean. Interestingly, the coating shows self-cleaning properties even when polluted by oil as shown in Fig. 7d–f. When the surface coating was contaminated by oil, the surface structures locked the oil as a lubricating layer, and the lubricated rough surfaces were capable of maintaining droplet mobility regardless of the wetting state. Soil and dust could also be removed by passing water over the surface (Video S5 in ESI†). Therefore, the surfaces retained their self-cleaning properties even after contamination by oil in air.

3.5. Oil–water separation

Materials with extreme wettability, such as superhydrophobic and superoleophilic properties, have been widely used in oil water separations.³³ However, it is not easy for oil/water separation in the real world because a large amount of polluted water needs to be accumulated first and then filtered. Herein, we used a vacuum system to realize the continuous separation of oil from water without any requirement for collection. Fig. 8a and b and Video S6† show that the oil and water can be separated with a sponge that is connected with a vacuum system. The silicone oil could be absorbed immediately by the sponge coated with SiO₂/PU and completely separated from water. The sponge has good absorption capacities with 8–17 times its own weight (Fig. S7 in ESI†). Fig. 8c shows the oil/water separating efficiency, and it can be seen that the efficiency is above 95% for all the oil and organic solvents tested, indicating the high continuous separating efficiency. Note that the superhydrophobic PU sponge was recyclable. After being rinsed thoroughly with alcohol and dried, the as-prepared sponges could be reused for oil/water separation for many cycles, as shown in Fig. 8d. The separating efficiency is still more than 85% after 8 times of recycling.

4. Conclusion

In conclusion, we have demonstrated a facile and low-cost method to fabricate superhydrophobic coatings based on combination of polymers with surface functionalized silica nanoparticles. The translucent water-repellent coatings demonstrate mechanical durability, acid/alkaline and UV resistance, and self-cleaning properties even when polluted by

oil. Importantly, the fluorine-free coatings have strong adhesion to the substrate and can also be healed by flame treatment. The substrate-independent synthesis provides researchers with new avenues for designing robust superhydrophobic coatings for large-scale indoor and outdoor applications.
