Effect of hydrogen diffusion in an In–Ga–Zn–O thin film transistor with an aluminum oxide gate insulator on its electrical properties†

Yunyong Nam,a Hee-Ok Kim,b Sung Haeng Cho b and Sang-Hee Ko Park*a

We fabricated amorphous InGaZnO thin film transistors (a-IGZO TFTs) with aluminum oxide (Al2O3) as a gate insulator grown through atomic layer deposition (ALD) method at different deposition temperatures (Td). The Al2O3 gate insulator with a low Td exhibited a high amount of hydrogen in the film, and the relationship between the hydrogen content and the electrical properties of the TFTs was investigated. The device with the Al2O3 gate insulator having a high H content showed much better transfer parameters and reliabilities than the low H sample. This is attributed to the defect passivation effect of H in the active layer, which is diffused from the Al2O3 layer. In addition, according to the post-annealing temperature (Tpost-ann), a-IGZO TFTs exhibited two unique changes of properties; the degradation in low Tpost-ann and the enhancement in high Tpost-ann, as explained in terms of H diffusion from the gate insulator to an active layer.

In addition to such intrinsic defects, hydrogen, as an impurity, can also affect the electrical properties of a-IGZO TFTs. Generally, it is known that hydrogen in crystalline-oxide semiconductors (e.g., c-ZnO and c-In2O3) acts as a source of high conductivity.2–4 Hydrogen in ZnO can exist in the form of interstitial H (HI) bonded with an oxygen atom and substitutional H (H0) located at an oxygen site. In both cases, positive charge states (H+ and HO−) are stable and act as a shallow donor in ZnO. Likewise, in a-IGZO, the role of hydrogen is mainly understood as a shallow donor, generating free carriers. It was revealed that the a-IGZO film itself has a high-density of hydrogen of 1020 to 1021 cm−3.7 Because excess H in an a-IGZO layer can lead to difficulty related to the control of Vth in the TFT, unexpected H should be avoided.

Recently, in several in-depth studies of H in oxide TFT, various effects were reported. Nomura et al. reported that all of H do not increase the conductivity of a-IGZO film due to the compensation of the free electrons by excess oxygen.7 Furthermore, an interesting role of H was reported in terms of defect passivation. Tsao et al. and Hanyu et al. reported an improvement in the transfer characteristics of a-IGZO TFTs when H was incorporated during active layer deposition and a post-annealing process, respectively.9,10 In addition, a beneficial effect of hydrogen on the reliability of a-IGZO TFTs was reported.10,11 However, the opposite effects of hydrogen, where it generates defect states and induces instability during photo-bias stress, were also reported.12–15

As described thus far, the role of H in a-IGZO TFTs remains unsolved. In addition, the difficulty in precise control of H in a-IGZO TFT makes the problem more difficult. Because H can be easily incorporated and/or diffused into the a-IGZO layer during

1. Introduction

Amorphous oxide semiconductors (AOSs) have been studied intensively as active channel layers for thin film transistors (TFTs) for next-generation displays owing to their scalability and high mobility. Generally, Zn-based AOSs are n-type semiconductors with mobility levels proportional to the carrier concentration.1 Among the various AOSs, In–Ga–Zn–O (a-IGZO), which is the best known composition, can exhibit a wide range of electron densities (Ne) ranging from 1011 to 1019 cm−3.2 Although a higher Ne is preferred for high mobility, this value must be carefully controlled because an a-IGZO TFT for which Ne is too high cannot be turn-off. In a-IGZO films, various intrinsic defects such as metal/oxygen vacancies and interstitials exist, and they mainly determine the electrical properties of the oxide TFT. Many studies have been conducted in an effort to reveal the effects of such defects on a-IGZO TFTs, and it is accepted that oxygen vacancies (Vo) serve as shallow donors in a-IGZO film and as a source of free carriers, while weakly bonded O acts as an electron trapping center.1–4 Therefore, controlling O in a-IGZO film is a key factor to optimize the electrical property of the TFT.

the fabrication of TFT devices, an experimental design capable of revealing the role of H in a-IGZO TFT is not straightforward. Specifically, SiO₂ and SiNx layers, which are widely used as gate insulators or passivation layers, are deposited through a plasma-enhanced chemical vapor deposition (PECVD) process, which can induce too much hydrogen in the film, complicating the proper control of H.11-13 To solve this problem, an Al₂O₃ layer can be used due to its excellent diffusion barrier property against hydrogen.14,15 In addition, Al₂O₃ is usually deposited through the atomic layer deposition (ALD) method, and the H concentration in Al₂O₃ can be controlled by the deposition temperature.16

In this work, the effects of H on the characteristics of a-IGZO TFT with Al₂O₃ as a gate insulator were examined. The amount of H in the Al₂O₃ layer was controlled by varying the deposition temperature (T_{dep}) used during the ALD method. Additionally, pre-annealing of the Al₂O₃ gate insulator was applied to control the H content in the film. The transfer parameters of a-IGZO TFTs such as the hysteresis, sub-threshold swing (S.S.) and mobility were then studied in relation to the H content in the Al₂O₃ gate insulator. In addition, according to the post-annealing temperature (T_{post-ann}), certain changes in the transfer parameters were investigated with regard to H diffusion in an a-IGZO TFT. The results showed that the amount of H in an active channel can easily be changed, and this amount determines the electrical properties of a-IGZO TFTs, including their reliability under bias temperature stress.

2. Experiment
An amorphous indium–gallium–zinc oxide (IGZO) TFT with a bottom gate bottom contact (BGBC) structure was fabricated, the schematic experimental flow of which is shown in Fig. 1. A patterned In–Sn–O (ITO) gate electrode was formed by a wet-etching process using a 150 nm-thick ITO-coated glass substrate. The aluminum oxide (Al₂O₃) gate dielectric layers were deposited by atomic layer deposition (ALD) method at deposition temperatures (T_{dep}) of 150 °C and 300 °C. Tri-methyl-aluminum (TMA, C₈H₂Al, 99.9999%) and water were used as an aluminum and oxygen source, respectively. The deposited Al₂O₃ layers were wet-etched to open the gate electrode. Then, the 150 nm-thick ITO was deposited by sputtering, followed by wet-etching for the source and drain electrodes. Before the wet-etching of the ITO, the samples were pre-annealed at 250 °C in a vacuum for 2 h to achieve low resistivity and to ensure good etching of the ITO layer. During this step, several samples were additionally annealed at higher temperatures of 300 °C and 350 °C under a vacuum for 2 h to modify the degree of H content in Al₂O₃. The active channel of the a-IGZO film (thickness of 40 nm and a metal ratio of In : Ga : Zn = 1 : 1 : 2.5) was deposited by sputtering at room temperature with an Ar/O₂ gas ratio of 6 : 4 and was then patterned by wet-etching. For a passivation layer, a 100 nm-thick SiO₂ layer was deposited by plasma-enhanced chemical vapor deposition (PECVD) using silane (SiH₄) and nitrous oxide (N₂O) gas at 300 °C. Subsequently, the SiO₂ layer was etched for the electrode contact. Finally, the fabricated IGZO TFTs were post-annealed in a range of T_{post-ann} = 200–400 °C under a vacuum for 2 h.

To determine the amount of hydrogen in the Al₂O₃ films, MS-SIMS (IMS 7f, CAMECA) and TOF-SIMS (TOF-SIMS5, ION-TOF GmbH) were used. The cesium (Cs⁺) primary ion beam with current of 15 nA and raster size of 200 μm × 200 μm was used. In addition, the FT-IR microscope (HYPERION 3000, Bruker Optiks) was also used with attenuated total reflectance (ATR) mode. Chemical composition was examined by XPS (K-alpha, Thermo VG Scientific). The data were collected after Ar sputtering for 15 s in an ultra-high vacuum (base pressure of ~10⁻⁹ torr). For the calibration, the Ar 2p peak of 241.9 eV was used. The electrical properties of the Al₂O₃ gate insulators and a-IGZO TFTs were measured using an Agilent 4284A precision LCR meter and B4156A semiconductor parameter analyser with a probe station.

3. Results and discussion
3.1. Characteristics of the ALD-Al₂O₃ gate insulator deposited at temperatures of 150 °C and 300 °C
First, to reveal the amount of hydrogen of the Al₂O₃ depending on T_{dep}, a SIMS analysis was conducted with the T_{dep} = 150 °C and 300 °C films. These results are shown in Fig. 2(a). The SIMS spectra clearly show a difference in the H content on the films; more H with a lower T_{dep} for the Al₂O₃ film was noted. This result can be easily understood by considering that, during the ALD process, the growth of the Al₂O₃ layer is mainly governed by the deposition temperature (T_{dep}). Generally in ALD, a higher value of T_{dep} leads to a lower growth rate and denser film. The residual H in low temperature ALD-Al₂O₃ growth occurs as a result of the incomplete removal of the hydroxyl group during the surface reaction. A high T_{dep} can facilitate a full sub-reaction between the chemisorbed Al–OH precursor and the gas phase.
hydrogen and/or carbon impurities will remain on the Al2O3 reactions and an insulator layers, absorption peak in the range of 3000 cm⁻¹ was observed in both Al2O3 – C and 3000 cm⁻¹ Al2O3 OH peak intensity, in good agreement with the SIMS analysis was conducted. The XPS results (see Fig. S1†) exhibited only Al 2p and O 1s peaks in all ranges, providing evidence of the formation of an Al2O3 layer without any impurities, such as carbon-related species. According to the Tdep value of the Al2O3 layer, the atomic percentages of Al and O were nearly identical, showing ratios of 42.83 : 57.17 and 43.1 : 56.9 for Tdep = 150 °C and 300 °C, respectively. In addition, no changes were found after annealing at 350 °C in a vacuum for 2 h.

3.2. Changes in the electrical properties of the a-IGZO TFT with ALD-Al2O3 gate insulator at Tdep = 150 °C (HH) and 300 °C (LH) depending on the post-annealing temperature (Tpost-ann)

Fig. 3 shows the variation in the transfer characteristics such as the hysteresis, subthreshold swing (S.S.) and mobility of a-IGZO TFTs with the ALD-Al2O3 gate insulator for Tdep = 150 °C (HH) and 300 °C (LH) according to various post-annealing temperatures (Tpost-ann = 200–400 °C). The individual transfer curves and parameters are listed in Fig. S2 and Table S1,† respectively. The transfer parameters of the hysteresis, subthreshold swing (S.S.), and mobility showed large variations and interesting trends according to (1) the hydrogen content in the Al2O3 gate insulator and (2) the post-annealing temperature of the a-IGZO TFTs.

First, with regard to the hydrogen content, the a-IGZO TFT with the high-hydrogen Al2O3 gate insulator (HH-device) showed much better transfer properties compared to the low-hydrogen (LH) device throughout the Tpost-ann range of 200–400 °C. In addition, the HH-device exhibited minor variation of the transfer parameters during the post-annealing step. The device showed the best properties at Tpost-ann = 300 °C, becoming nearly saturated when Tpost-ann exceeded 300 °C. In contrast, the LH device showed greatly deteriorated properties, exhibiting much larger hysteresis, S.S. and lower mobility values.

This result can be explained by the different amounts of H in the Al2O3 gate insulators. As depicted in the SIMS results, the Tdep = 150 °C Al2O3 layer has more H in the film compared to the Tdep = 300 °C sample. This H can easily diffuse toward the a-IGZO active layer during the fabrication and/or post-annealing processes. Here, it should be noted that the SiO2 passivation layer was deposited at 300 °C. The H which diffuses from the Al2O3 gate insulator passivates the defects in the a-IGZO film and improves its TFT properties, as reported in a number of studies. The improvements of the S.S. value and mobility are mainly related to the electron trap sites, which indicates that the devices with higher H concentrations have fewer electron traps in the a-IGZO channel. In addition, several shallow trap sites located in the gate insulator, generated from the plasma during the a-IGZO deposition step, can also be passivated by H, resulting in an improvement of the hysteresis.

The basic characteristics of the ALD-deposited Al2O3 gate insulator layers, i.e. the dielectric constant (k) and the chemical composition, including the amount of H, were then examined. Using ITO/Al2O3/ITO (MIM) devices annealed at a temperature of 350 °C, the dielectric constants (k) were extracted. The measured frequency of the capacitance–voltage curves was 1 MHz, and the size of the measured square pad was 300 × 300 μm. The HH- (high hydrogen for Tdep = 150 °C) and LH- (low hydrogen for Tdep = 300 °C) Al2O3 layers showed k values of 7.67 and 7.76, respectively, as shown in Fig. 2(c). The higher deposition temperature of the Al2O3 layer resulted in a slightly increased dielectric constant. As previously reported, the Tdep of ALD-Al2O3 scarcely affects the dielectric constant in the range of 150–300 °C. In addition, after the Al2O3 layers were annealed up to 400 °C, no changes in the dielectric constant were noted (data not shown). To confirm the chemical composition of the Al2O3 layers according to Tdep, the XPS analysis was conducted. The XPS results (see Fig. S1†) exhibited only Al 2p and O 1s peaks in all ranges, providing evidence of the formation of an Al2O3 layer without any impurities, such as carbon-related species. According to the Tdep value of the Al2O3 layer, the atomic percentages of Al and O were nearly identical, showing ratios of 42.83 : 57.17 and 43.1 : 56.9 for Tdep = 150 °C and 300 °C, respectively. In addition, no changes were found after annealing at 350 °C in a vacuum for 2 h.
Additionally, interesting behaviors of the transfer parameters of a-IGZO TFTs were observed according to post-annealing temperature. First, in the high \( T_{\text{post-ann}} \) (300–400 °C) case, the transfer parameters were dramatically improved. Specifically, this outcome was observed in the LH devices. The LH a-IGZO TFT showed hysteresis of 11.25 V, S.S. of 0.3 V dec\(^{-1}\) and mobility of 1.5 cm\(^2\) V\(^{-1}\) s\(^{-1}\) at \( T_{\text{post-ann}} = 250 \) °C. These values were improved to 2.52 V, 0.16 V dec\(^{-1}\) and 14 cm\(^2\) V\(^{-1}\) s\(^{-1}\), respectively, when the device was post-annealed at 350 °C. These parameters were mostly saturated past 350 °C. This large improvement can be attributed to the defect passivation of hydrogen which is diffused to the a-IGZO layer from the Al\(_2\)O\(_3\) gate insulator during the high temperature annealing process.

The SIMS analysis results [Fig. 4] clearly verify this approach, showing hydrogen diffusion after post-annealing at a high temperature. For the SIMS analysis, a SiO\(_2\)/a-IGZO/Al\(_2\)O\(_3\) (\( T_{\text{dep}} \) of Al\(_2\)O\(_3\) = 300 °C) sample, which has a structure identical to that of a TFT, was prepared and annealed at 400 °C. When the annealing at 400 °C, the H intensity in the Al\(_2\)O\(_3\) layer deceased. On the other hand, in the a-IGZO layer, the amount of H increased. This result strongly suggests that H in the Al\(_2\)O\(_3\) layer diffuses into the a-IGZO layer, with this causing the passivation of the defects in the a-IGZO layer. Although the Al\(_2\)O\(_3\) layer is known to be an excellent H diffusion barrier, the effusion of H can take place within several nano-meters of alumina during high temperature annealing at about 400 °C.\(^{25,26}\) It is believed that the amount of H which diffused is small because the turn-on voltage (\( V_{\text{on}} \)) of the a-IGZO TFT was kept at 0 V during the 400 °C annealing process. Here, it is noted that H in the SiO\(_2\) passivation layer can also diffuse during the annealing and affect the electrical properties of the a-IGZO TFTs. In the SIMS results, the decreased H intensity in passivation layer (SiO\(_2\)), however, was observed in the surface rather than the inner region of SiO\(_2\) layer. This indicates that H mainly diffuses toward out to the surface. This could be because the annealing was conducted in a vacuum condition.

On the other hand, in the range of low \( T_{\text{post-ann}} \) (200–250 °C), the a-IGZO TFTs showed more deteriorated transfer curves compared to those of the as-fabricated devices, exhibiting larger hysteresis and lower mobility levels. For the LH device, the hysteresis and S.S. value increased to 11.25 V and 0.3 V dec\(^{-1}\) after annealing at 250 °C from 8 V and 0.18 V dec\(^{-1}\) (in the as-fabricated case), respectively. The mobility also decreased to 1.5 cm\(^2\) V\(^{-1}\) s\(^{-1}\) from 3.95 cm\(^2\) V\(^{-1}\) s\(^{-1}\). The results can be explained by the de-passivation effect of H in the a-IGZO layer through the PECVD SiO\(_2\) passivation film during the post-annealing step. The as-deposited a-IGZO layer contains a large amount of H itself, which is incorporated during the deposition process.\(^{15}\) This H can passivate some defect states in the a-IGZO film. However, a heat-treatment could lead to the de-passivation of H, generating new defect states in the a-IGZO layer. Previously, Hanyu et al. reported a similar de-passivation effect of hydrogen with dry-O\(_2\) annealing at \( T_{\text{post-ann}} = 400 \) °C with a-IGZO TFTs without a passivation layer.\(^{8}\) In this work, however, it starts at a much lower temperature of about 200 °C; we think that this is attributed to the difference in the device structures and the annealing atmospheres (in this work, a SiO\(_2\) passivation layer...
and vacuum annealing were used). Actually, Noh et al. reported a simulation result which indicates that H₂O (H occupies the oxygen vacancy site, H₁ + V₀) decreases rapidly past an annealing temperature of 180 °C.⁴⁸

Here, it should be noted that the H diffusion effect from the Al₂O₃ to the a-IGZO during Tₚₒˢᵗ-ₜᵢₜₛₐₜ = 200–250 °C is minimized due to the pre-annealing process of the Al₂O₃ gate insulator at 250 °C. As displayed in Fig. 1, during the fabrication process, there is a pre-annealing step for ITO/Al₂O₃/ITO samples at 250 °C in a vacuum for 2 h to improve the ITO quality. During this pre-annealing step, the H in the Al₂O₃ layer is effused to a vacuum beforehand, as this step is performed without an a-IGZO layer. Therefore, after the final fabrication of the a-IGZO TFTs, post-annealing below 250 °C can serve only a limited amount of H from the Al₂O₃ to the a-IGZO layer. Therefore, for the HH-device shown in Fig. 3, the transfer parameters were greatly improved not at Tₚ₂ₒˢᵗ-ₜᵢₜₛₐₜ = 200 °C, but at 300 °C.⁴⁹

In addition, the effect of H on the stability was investigated under negative and positive bias temperature stress (NBTS and PBTS, respectively). Gate bias (Vₑ) levels of −20 V and +20 V were applied at a temperature of 60 °C for 10,000 s for NBTS and PBTS, respectively, using an a-IGZO TFT which was post-annealed at 350 °C. This result is shown in Fig. 5. In the NBTS condition, both devices (HH- and LH-) showed excellent stability, exhibiting Vₑ shift values of +0.3 and +1 V, respectively, compared to those of the PBTS condition. This is attributed to the fact that there was a small hole in the a-IGZO film which can be trapped when in the NBTS condition. In contrast, Vₑ was greatly shifted by +4.9 and +15.1 V after PBTS for the HH- and LH-devices, respectively. From the parallel shift of the transfer curve without any degradation of the S.S. value, it is suggested that the main reason for the Vₑ shift in the PBTS condition is related to the trapping of electrons in the trap sites located in the a-IGZO and/or at a-IGZO/Al₂O₃ interface.⁵⁰ During the a-IGZO deposition process, damage at the surface of the gate insulator can be induced by the negative oxygen ion bombardment. This results in a high density of states for electron trapping which becomes more severe upon a higher level of PO₂.⁵¹ In this work, a relatively high level of PO₂ (40%) was used, which would lead to poor stability against PBTS. In addition, the PECVD process for the SiO₂ passivation layer generates excess oxygen in the a-IGZO film, resulting in oxygen interstitial (O–O₂) related states.⁵² These O₂ defects easily capture electrons and act as electron traps, resulting in positive shifts of Vₑ under positive-bias stress condition.⁵³,⁵⁴ To achieve better stability of the a-IGZO TFTs, an a-IGZO layer with the low PO₂ condition and/or a protective layer such as ALD-grown Al₂O₃ would be introduced.⁵⁵ Though both devices showed poor PBTS stability, it is clear that the HH-device is more stable than the LH-device. This result suggests that the defect passivation effect of H is still valid with regard to PBTS stability for the suppression of electron trap sites.

In addition to the annealing temperature, annealing time can also affect the electrical property and stability of the a-IGZO TFTs. To examine the effect of annealing time, we increased annealing time to 4 h and 6 h for HH- and LH-devices at 350 °C, and results are shown in Fig. S3 and S4.† For the HH-device, the transfer curves showed similar parameters according to annealing time. On the other hand, the LH-device exhibited improved transfer characteristics showing smaller hysteresis and higher mobility as annealing time increased. In the PBTS results, HH- and LH-device showed smaller Vₑ shift of +1.54 V and +6.16 V, respectively, after longer annealing process of 6 hours. This results suggest that H continues to diffuse into the active layer from the Al₂O₃ layer and passivate defects in the active layer and/or interface between the gate insulator and active.

**3.3. Changes in the electrical properties of the a-IGZO TFT with an ALD-Al₂O₃ gate insulator for Tₜₑₕₑᵈₜ = 150 °C (HH) depending on the pre-annealing temperature (Tₚₑᵦᵝ-ᵣₑᵦ)***

As noted above, during the fabrication process of the a-IGZO TFT, there is a pre-annealing step of the Al₂O₃ layer at 250 °C which affects the evolution of the transfer parameters according to Tₚ₂ₒˢᵗ-ₜᵢₜₛₐₜ due to H effusion. To investigate this approach further, we increased the pre-annealing temperatures to 300 °C and 350 °C from 250 °C in the HH-device. Summary plots of the transfer parameters, in this case the hysteresis and S.S., are shown in Fig. 6(a) and (b), respectively (see Fig. S5, S6 and Table S2 for details†). The result for the HH-device with Tₚ₂ₒˢᵗ-ₜᵢₜₛₐₜ = 250 °C is also displayed for comparison as a reference result.

The result clearly showed behaviors identical to those discussed above. First, when Tₚₑᵦᵝ-ᵦₑᵦ is increased, the devices showed more deteriorated transfer characteristics in the as-
showed the recovery of the transfer parameters at post-annealing related to the de-passivation of H in the a-IGZO layer. This non-annealing, and it leads to poor transfer curves. In addition, past the reference devices. The characteristics were fully recovered to a level similar to those of fabricated samples. This behavior is identical to that in the LH-devices (see Fig. 3), which have less H in the Al2O3, and it is fabricated and used to control the active layer during post-annealing. This is explained by the effusion of H in the a-IGZO layer through the SiO2 passivation layer in terms of de-passivation of H. Additionally, the H contents in the Al2O3 layer were controlled by varying the pre-annealing temperature (200–350 °C), the devices showed more deteriorated transfer curves compared to those before annealing. This is explained by the effusion of H in the a-IGZO layer through the SiO2 passivation layer in terms of de-passivation of H. Additionally, the H contents in the Al2O3 layer were controlled by varying the pre-annealing temperature (200–350 °C), the devices showed more deteriorated transfer curves compared to those before annealing. This non-passivation effect became more severe as Tpre-ann was increased because H was more effectively diffused and could not be supplied to the active layer. However, when the devices were post-annealed at a higher temperature than Tpre-ann, the transfer characteristics were fully recovered to a level similar to those of the reference devices. The Tpre-ann = 300 and 350 °C devices showed the recovery of the transfer parameters at Tpost-ann = 350 and 400 °C, respectively. These outcomes indicate that H can be diffused and passivate defects in the a-IGZO layer when annealing takes place at a higher Tpost-ann than Tpre-ann.

The PBTS stability was also measured after Tpost-ann = 400 °C, and the result is shown in Fig. 6(c). Although both devices with Tpre-ann = 300 and 350 °C showed transfer curves similar to those of the reference sample, the PBTS test showed quite different result. Compared with the ΔVon of +4.8 V for the reference, the Tpre-ann = 300 and 350 °C devices showed large ΔVon values of 6.58 and 9.8 V, respectively. These results indicate that, even though defect passivation effect of H can effectively improve the transfer characteristics, there still appears to be other deep traps in the gate insulator.

4. Conclusions

In summary, we performed experiments to reveal the effect of hydrogen diffusion on a-IGZO TFTs with Al2O3 gate insulator. The device with a high level of H in the Al2O3 exhibited excellent properties, including transfer parameters and bias temperature stabilities as compared to sample with low H levels. The SIMS results showed that H in the Al2O3 layer was diffused into the a-IGZO layer after post-annealing at 400 °C, suggesting that H has a beneficial effect on the TFT properties in terms of defect passivation. On the other hand, at a low post-annealing temperature (200–250 °C), the devices showed worse hysteresis and S.S. values compared to those before annealing. This is explained by the effusion of H in the a-IGZO layer through the SiO2 passivation layer in terms of de-passivation of H. Additionally, the H contents in the Al2O3 layer were controlled by varying the pre-annealing temperature, and the defect passivation and de-passivation effects of H were examined in greater depth.
