Scope of sulfur dioxide incorporation into alkyldiallylamine–maleic acid–SO₂ tercyclopolymer†

Ibrahim Y. Yaagoob, Shaikh A. Ali,* Hasan A. Al-Muallem* and Mohammad A. J. Mazumder

Alternate copolymerization of diallylamine derivatives [(CH₂=CH–CH₂)₂NR; R = Me, (CH₂)₃PO(OEt)₂, and CH₄PO(OEt)₂] and maleic acid (MA) and (I-HCl)–SO₂ pairs have been carried out thermally using ammonium persulfate initiator as well as UV radiation at a λ of 365 nm. The reactivity ratios of = 0 for the monomers in each pair I–MA and I-HCl–SO₂ ensured their alternation in each copolymer. However, numerous attempted terpolymerizations of I–MA–SO₂ failed to entice MA to participate to any meaningful extent. In contrast to reported literature, only 1–2 mol% of MA was incorporated into the polymer chain mainly consisting of poly(I-alt-SO₂). Quaternary diallyldialkylammonium chloride [(CH₂=CH–CH₂)₂N⁺R₂Cl⁻; R = Me, Et] also, did not participate in II–MA–SO₂ terpolymerizations. Poly(III, R = Mel-alt-SO₂) III is a stimuli-responsive polyampholyte; its transformation under pH-induced changes to cationic, polyampholyte-anionic, and dianionic polyelectrolytes has been examined by viscosity measurements. The pKₐ of two carboxylic acid groups and NH⁺ in III has been determined to be 2.62, 5.59, and 10.1. PA III, evaluated as a potential antiscalant in reverse osmosis plants, at the concentrations of 5 and 20 ppm, imparted ≈100% efficiency for CaSO₄ scale inhibition from its supersaturated solution for over 50 and 500 min, respectively, at 40 °C. The synthesis of PA III in excellent yields from cheap starting materials and its very impressive performance may grant PA III a prestigious place as an environment-friendly phosphate-free antiscalant.

1. Introduction

Butler’s cyclopolymerization protocol has etched a place of distinction in the synthesis of polymers of tremendous technological importance. Free radical-initiated polymerization of diallylammonium salts A led to B having pyrrolidone rings embedded into the macromolecules (Scheme 1). The macromolecule B represents the eighth most important architecture among synthetic high polymers. Polydiallyldimethylammonium chloride B (R¹=R²=Me), alone accounting for over 1000 patents and publications, has been produced to the tune of millions of pounds for a variety of industrial applications including water treatment. Sulfur dioxide has been extensively used to synthesize alternate cycopolymers C having numerous applications. The reactivity ratios of amine [salt] (rₐ) and r₅O₂ being zero led to the alternation in C. Likewise, the almost zero reactivity ratios of rₐ and maleic acid (MA) (r₅MA) led to the exclusive formation of alternate copolymer D from alkyldiallylamine/MA ion pair A. Interestingly, diallyldimethylammonium chloride (A)–MA–SO₂ is reported in several patents to give terpolymers in respective ratios of 50 : 25 : 25 (ref. 12) and 70 : 25 : 5. However, the patents do not describe any micro-structural analysis. To our knowledge, no journal article has appeared to date to describe such terpolymerization involving A–maleic acid–SO₂ to give E (Scheme 1).

Amino-carboxylate and -phosphonate are important antiscalant and metal chelation motifs; as such, the decoration of repeating units with a high density of these potent functional groups is expected to impart, for instance, an antiscalant behavior. Looking at the zero reactivity ratios for both the monomer pairs: rₐ = r₅O₂ ≈ 0 and rₐ = r₅MA ≈ 0 (Scheme 1), we do fancy the success of the terpolymerization to pave the way to a great many interesting tripolymers E. Herein, we report a systematic study involving the cyclopolymerization of A, A–SO₂, A–MA, and A–MA–SO₂ to investigate the course of action of an amine terminal radical ‘A’ whether it adds exclusively or preferentially onto SO₂ or MA or both.

2. Experimental section

2.1 Materials

Paraformaldehyde was purchased from Fluka Chemie AG. Diallylamine from Merek Schuchardt OHG, ammonium persulfate (APS), azobisisobutyronitrile (AIBN) and maleic acid from Sigma-Aldrich were used as received. Diallyldimethylammonium...
chloride (15a) from Sigma-Aldrich, obtained as 65 wt% solution, was freeze-dried and crystallized from methanol/acetone. Phosphonate ester 1a, 1b, and 5 (ref. 17) were prepared as described.15–17 For dialysis, Spectra/Por membrane (MWCO: 6000–8000) from Spectrum Laboratories Inc. was utilized.

2.2 Physical methods

Elemental analysis was carried out in a Perkin Elmer Elemental Analyzer Series 11 Model 2400 (Waltham, Massachusetts, USA). IR spectra were recorded on a Thermo Scientific FTIR spectrometer (Nicolet 6700, Thermo Electron Corporation, Madison, WI, USA). 1H and 13C NMR spectra of the polymers were measured in D2O on a JEOL LA 500 MHz spectrometer. The residual HOD signal of D2O at δ 4.65 ppm and dioxane 13C resonance at δ 67.4 were used as internal and external references, respectively. Viscosities were measured using an Ubbelohde viscometer (viscometer constant = 0.005718 cSt s-1). An SDT analyzer (Q600: TA instruments, USA) was utilized for Thermogravimetric analysis (TGA) under N2 flowing at a rate of 50 cm3 min-1. For photoinitiated polymerization, the samples were irradiated at 365 nm using UV Lamp 365 nm/254 nm SPECTROLINE (Model: ENF-240C) from Spectronic Corp., Westbury, NY, USA, with LONGLIFE Filter to ensure highest UV intensity and Fluorescence Analysis Cabinet SPECTROLINE CM-10A.
2.3 Synthesis of methyldiallylamine (7) and its hydrochloride salt 8

The procedure for the methylation of amines is adapted from the literature. Formic acid (35 g, 85%, 0.646 mol) was added slowly (30 min) onto an ice-cold diallylamine (1) (49 g, 0.506 mol) in a 1 L RB flask under stirring. Paraformaldehyde (18.3 g, 0.613 mol) and water (33 mL) were added to the flask. The mixture in the flask, fitted with a long condenser, was stirred at 75–77 °C during which CO₂ evolution happened (30 min). Thereafter, the reaction mixture was heated to 90 °C; after the gas evolution stopped (15 min), the reaction mixture was cooled and saturated with the addition of a solution of NaOH (30 g, 0.75 mol) in water (30 mL). The separated organic layer of amine 7 was dried over NaOH and distilled at 107 °C (lit. 90 °C) to obtain 7 as a colorless liquid (49 g, 87%).

A dry HCl gas was passed to a solution of methyldiallylamine (7) (25 g, 0.225 mol) in ether (150 mL) at 0 °C. Immediate precipitation of white salt 8 occurred. The passage of HCl was continued until the supernatant liquid becomes clear instead of cloudy. After filtration, the white salt was dried under vacuum to obtain 8 (30 g, 90%). δ₂1(D₂O) 2.70 (3H, s), 3.65 (4H, d, J 7.3 Hz), 5.50 (4H, m), 5.82 (2H, m); δC(D₂O) 39.57 (1C, Me), 58.30 (2C, NCH₃), 126.60 (2C, =CH), 127.33 (2C, =CH₂). The ¹³C spectral assignments was supported by DEPT 135 NMR analysis.

2.4 Polymer syntheses

2.4.1 Procedure for 1 or 5/2/SO₂ terpolymerization. Table 1 describes the polymerizations conditions (Scheme 1). For experiment under entry 1, SO₂ (705 mg, 11 mmol) was absorbed in a solution of monomer 1a (1.38 g, 5.0 mmol) and MA 2 (0.70 g, 6.0 mmol) in DMSO (2.6 g) in an RB flask (10 mL). After purging the mixture with N₂, initiator APS (0.260 g) was added to the stirring mixture in the closed flask at 21 °C for 24 h. The polymer mixture was dialyzed against 0.2 M HCl for 24 h with frequent change of distilled water for 6 h. The dialyzed solution was acidified with concentrated HCl (1.0 mL) and freeze-dried to obtain 4a. Note that the acidification was intended to keep the nitrogens and carboxyls protonated. The FTIR and NMR spectra of the polymers resembled with the spectra of 1a HCl/SO₂ and 1b HCl/SO₂ copolymers 4a⁻¹⁸ and 4b⁻¹⁹ (y = 0), respectively.

For the polymerization involving monomer 5, the crude reaction mixture was dialyzed against 2 M HCl followed by deionized water. Polymer 6 (y = 0), precipitated out during dialysis, was dried under vacuum. The spectral analysis revealed the identical nature of the material 6 (y = 0) described elsewhere.²⁰

2.4.2 Free radical polymerization of monomer 8. A solution of salt 8 (8.86 g, 60 mmol) in water (3.5 g) and concentrated HCl (36 wt%) (0.5 g) in an RB flask (50 mL) fitted with a condenser was degassed with N₂ and then heated to 100 °C. APS was added in three portions (3 × 250 mg) with intervals of 3 min (Scheme 2). The temperature of the exothermic polymerization rose to 110 °C. The reaction mixture was continued to stir at the oil bath temperature of 110 °C for an additional 30 min. The product mixture was then dialyzed against distilled water and freeze-dried to obtain polymer 9 (7.7 g, 87%) as a white powder. (Found: C 56.7; H 9.58; N 9.4%. C7H14ClN requires C 56.94; H 9.56; N 9.56%).

2.4.3 Photochemically initiated polymerization of monomer 8. A sample of monomer 8 (200 mg, 1.4 mmol) in a vial was exposed to UV radiation at room temperature for 4 days. No polymerization occurred as indicated by ¹H NMR spectrum. Likewise, a solution of monomer 8 (295 mg, 2.0 mmol) in water (120 mg) was exposed to UV radiation at room temperature for 4 days giving 9 only in 5% yield as revealed by ¹H NMR spectrum. The yield was improved to 7.6% after further irradiation for 2 days.

2.4.4 Copolymerization of 8 with SO₂. To a solution of monomer 8 (5.02 g, 34 mmol) in DMSO (8.4 g) was absorbed SO₂.

**Scheme 2** Synthesis of homopolymer from 8, alternate copolymers from 7/MA, 15/MA, 8/SO\(_2\), 15/SO\(_2\), and terpolymers from 7 or 8/MA/SO\(_2\) and 15/MA/SO\(_2\). 

**2.4.5** Methyldiallylamine (7) and maleic acid (2) ion pair 12. Maleic acid 2 (1.16 g, 10.0 mmol) was added to a biphasic mixture of amine 7 (1.11 g, 10.0 mmol) in water (8 mL) and stirred at 25 °C for 30 min. Exothermic neutralization led to a homogeneous solution which was freeze-dried to obtain ion pair 12 as a colorless liquid in quantitative yield. \( \nu_{\text{max}} \) (neat): 3496 (strong), 3375 (strong and broad), 3031, 2962, 2656 (R\(_3\)NH\(^+\)), 2516 (R\(_3\)NH\(^+\)), 2356 (R\(_3\)NH\(^+\)), 1704, 1623, 1581, 1477, 1363, 1202, 1082, 898, 869, 710, 653, and 568 cm\(^{-1}\); \( \delta \) (D\(_2\)O) 2.55 (3H, s), 3.43 (2H, ABX, \( J \) 7, 13.4 Hz), 3.57 (2H, ABX, \( J \) 7, 13.4 Hz).
2.4.6 Copolymerization of 7 and MA 2. In an RB flask fitted with a condenser, were taken amine 7 (2.22 g, 20.0 mmol), MA 2 (2.54 g, 22.0 mmol) and water (2.04 g). The homogeneous mixture was stirred at 100 °C under N2, and initiator APS was added (2 × 200 mg) onto the mixture over 4 min. The exothermic polymerization started, and the mixture was stirred at 100 °C (10 min), cooled, dialyzed against deionized water, and freeze-dried to obtain a white powder of alternate polymer 14 having a monomer conversion of 86% as indicated by 1H NMR spectrum. (Found: C 57.8; H 7.7; N 6.0%. C11H17NO4 requires C 58.14; H 7.54; N 6.16%). \[\text{max (KBr): 3455 (broad), 2949, 2729, 2357, 1714, 1635, 1574, 1464, 1391, 1207, 1053, 810, 661 and 566 cm}^{-1}\].

2.4.7 Procedure for 7 or 8/2/SO4 terpolymerization. Table 2 describes the polymerizations conditions. The polymerizations were carried out as described under Section 2.4.1. After completion of the polymerization, the crude mixture was dialyzed against 0.2 M HCl with frequent change of the 0.2 M HCl for a duration of 24 h, and finally, dialyzed against distilled water for 6 h. The resulting solution was acidified with concentrated HCl (1.0 mL) and freeze-dried to obtain polymer 14. Note that the acidification was carried out to keep the nitrogens and carboxyls protonated. The FTIR and NMR spectra of the polymer 14 resembled with the spectra of the monomers 7 and MA. The results of APS-initiated terpolymerization of monomers 1a or 1b or 5 with SO2 and MA 2 are given in Table 1 (Scheme 1). The attempted copolymerization of MA–SO2 was unsuccessful (entries 13 and 14). Terpolymerization of 1a–MA–SO2 was conducted under various conditions using APS or AIBN initiator. The polymer 4a was isolated after extensive dialysis against aqueous HCl to remove unreacted MA and replace the maleate anion with Cl− ions. The spectral (NMR and IR) analysis of 15/2/SO2 co- and terpolymerization. Table 3 describes the polymerizations conditions (Scheme 2). The polymerizations of monomers 15 were carried out as described under Section 2.4.1. After the elapsed time, the reaction mixture (involved MA) was dialyzed against 0.5 M HCl for 24 h with frequent change of the 0.5 M HCl to remove excess MA, followed by dialysis against distilled water for 6 h. The resulting solution freeze-dried to obtain polymer 16. However, the dialyzed solution of 18, after acidification with concentrated HCl (1.0 mL), was freeze-dried. (Acidification was carried out to keep the carboxyl groups protonated). In the case where MA was not involved, the polymer 17 was simply purified by dialysis against distilled water. The FTIR and NMR spectra of the polymer 18 resembled with the copolymer 17, thereby implying the value of \( \gamma = 0 \).

2.5 Determination of basicity constants by titrations The basicity constant (K) of the three basic centers in PA 13 were determined using reported procedures and conditions described in Table S1. + log KS were calculated using the Henderson–Hasselbalch equation (eqn (2); Scheme 3).

2.6 Use of synthesized PA 13 as an antiscalant The inhibition of CaSO4 scale formation from its supersaturated solution was examined in the presence of various concentrations of PA 13 in an aqueous solution containing Ca2+ (2600 mg L−1) and SO42− (6300 mg L−1) at 40 ± 1 °C as described. The conductivity decreased suddenly after an induction time, owing to the formation of scale as confirmed by visual inspections.

3. Results and discussion

3.1 Polymer synthesis

The results of APS-initiated terpolymerization of monomers 1a or 1b or 5 with SO2 and MA 2 are given in Table 1 (Scheme 1). The attempted copolymerization of MA–SO2 was unsuccessful (entries 13 and 14). Terpolymerization of 1a–MA–SO2 was conducted under various conditions using APS or AIBN initiator. The polymer 4a was isolated after extensive dialysis against aqueous HCl to remove unreacted MA and replace the maleate anion with Cl− ions. The spectral (NMR and IR) analysis of 15/2/SO2 co- and terpolymerization. Table 3 describes the polymerizations conditions (Scheme 2). The polymerizations of monomers 15 were carried out as described under Section 2.4.1. After the elapsed time, the reaction mixture (involved MA) was dialyzed against 0.5 M HCl for 24 h with frequent change of the 0.5 M HCl to remove excess MA, followed by dialysis against distilled water for 6 h. The resulting solution freeze-dried to obtain polymer 16. However, the dialyzed solution of 18, after acidification with concentrated HCl (1.0 mL), was freeze-dried. (Acidification was carried out to keep the carboxyl groups protonated). In the case where MA was not involved, the polymer 17 was simply purified by dialysis against distilled water. The FTIR and NMR spectra of the polymer 18 resembled with the copolymer 17, thereby implying the value of \( \gamma = 0 \).
revealed that terpolymer 4a resembled the 1a–SO2 copolymer 4a (y = 0), except a minor 13C C=O peak at δ 180 ppm (vide infra) and a minor vibration at γ 1728 cm⁻¹ attributed to C=O of CO₂H in the IR spectrum. The absence of alkene carbons at δ 135 ppm excluded the presence of MA either as a free acid or the maleate ions; however, the presence of minor C=O signals suggests the incorporation of maleic acid into the polymer backbone. The MA does undergo propagation, but the addition is reversible as indicated by the presence of fumaric acid (FA) (trans-HO₂CC=CHCO₂H) in the unreacted reaction mixture, in addition to its original cis-counterpart MA in a ≈ 1 : 4 ratio. The radical having MA terminal: R–CH(CO₂H)–CH(CO₂H)− may undergo quick reversion to give R− and MA as well as FA.

Likewise, 1b–MA–SO₂ (entry 10) and 5–MA–SO₂ (Table 1, entries 11 and 12) terpolymizations afforded 4b and 6, respectively (Scheme 1), whose spectra are identical to those of 4b (y = 0) and 6 (y = 0), except that a very minor peak due to C=O in the 13C NMR and IR spectra indicate the very minor incorporation of MA.

Monomer 8 was homo- and co-polymerized with SO₂ to obtain cationic polyelectrolytes 9 and 10 in excellent yields of 87 and 93%, respectively (see Experimental) (Scheme 2). Homo-polymerization of 8 in an aqueous solution under UV light (λ = 365 nm) was very slow; after 6 days, it gave CPE 9 in a very low yield of 7.6% (entry 16, Table 2). The bulk photocopolymerization 8–SO₂ (entry 15, Table 2) in the absence of

* Viscosity of 1–0.0625% polymer solution in 0.1 N NaCl at 30 °C was measured with Ubbelohde viscometer (K = 0.005317 mm² s⁻¹). ° Conversion as revealed by 1H NMR of crude mixture. † White solid mixture in the beginning and no phase change throughout. ‡ Not been able to add more SO₂. § Slightly turbid in the beginning but hardened towards the end.

Scheme 3  pH Induced changes in the charge types in the backbone of 13, 19–21.
solvent gave CPE 10 having much higher intrinsic viscosity [η] of 0.836 dL g⁻¹ than that of the thermally initiated copolymer with a [η] of 0.276 dL g⁻¹ (Experimental section 2.4.4).

Terpolymerization of 7 or 8–MA–SO₂ was extensively studied using free radical initiators APS, AIBN or UV radiation at λ 365 nm (Scheme 2). The results are included in Table 2. Note that the isolated yields after dialysis are low as compared to the NMR conversion since the low molecular weight polymer fractions leave the dialysis bag. The 1H and 13C NMR spectra of the polymer.

(3a and 4) and 15b–SO₂ (entry 7) gave polymers 18a and 18b, respectively; their NMR and IR spectra matched with those of the respective copolymers 17a and 17b except the minor C=O vibration of CO₂H at ≈1728 cm⁻¹ were used to estimate the MA mol%.

Next, we focussed our attention to the polymerization of quaternary ammonium salts 15 as outlined in Scheme 2; the polymerization conditions and the results are included in Table 3. The 15a–MA copolymerization afforded 16a in 27% isolated yields, while the crude mixture before dialysis indicated 98% conversion as calculated from 1H NMR spectrum (entry 1). The spectral data matched with that reported for the polymer.²¹ Bulk copolymerization of 15a–SO₂ under UV light 14 afforded copolymer 17a in excellent yield (entry 2). The very high [η] value of 1.86 dL g⁻¹ indicated the high molar mass of the polymer. The thermal 15b–SO₂ (ref. 19) copolymerization afforded copolymer 17b also in excellent yields (entries 5 and 6). The IR and NMR spectra of 17a, b matched with the reported data.²²,²⁶ The terpolymerizations: 15a–MA–SO₂ (entries 3 and 4) and 15b–MA–SO₂ (entry 7) gave polymers 18a and 18b, respectively; their NMR and IR spectra matched with those of the respective copolymers 17a and 17b except the minor C=O vibration at ≈1728 cm⁻¹ indicating the incorporation of ≈1–3 mol% MA.

All the reactivity ratios in the pairs: amine salt–MA and amine salt–SO₂ are almost zero (vide supra) thereby implying that under the reaction conditions, amine salt or MA or SO₂ cannot undergo homopolymerization, instead they must give alternate copolymers as experimentally observed. MA–SO₂ reaction has been shown to give neither homo- nor co-polymer (entries 13 and 14, Table 1). In the numerous amine salt–MA–SO₂ terpolymerizations, the extent of MA incorporation is only 1–2 mol%. In every instance, amine salt–SO₂ copolymer was obtained and no trace of amine salt–MA copolymer could be identified. The claim in the patented literatures²²–²⁴ that the formation of terpolymer: diallyldimethylammonium chloride–maleic acid–SO₂ having repeating unit composition of 50 : 25 : 25 and 70 : 25 : 5 are doubtful. A composition ratio of 50 : 25 : 25 may indeed be a result of a mixture of two alternate copolymers of diallyldimethylammonium chloride–maleic acid and diallyldimethylammonium chloride–SO₂. The current work confirms that the amine salt–MA–SO₂ cannot be terpolymerized to any meaningful extent.

3.2 Solubility behavior

Cationic polymers 4a, b (y = 0), 9, 10 and 14 (y = 0) are water-soluble, while the PZ 6 (y = 0) is insoluble in water but soluble in 0.8 M HCl.²⁹ The water-solubility of 13, unlike most electro-neutral polymers,²⁷–²⁹ could be attributed to the less effective participation of the crowded CO₂⁻ to undergo electrostatic associations with NH⁺ for manifestation of ampholytic interactions.² Moreover, the hydrophilicity and solubility of the ampholytic motifs increase as a result of the increased dipole moment (μ) because of the large separation between NH⁺ and CO₂⁻.²⁰,³¹

3.3 Spectroscopic characterization

The strong IR bands at 1304 and 1128 cm⁻¹ were assigned to the vibrations of SO₂ unit in 10. The absorption band at ≈1714 and 1574 cm⁻¹ is attributed to the C=O stretch of CO₂H and CO₂⁻ in (+–) 13.²²

The NMR spectra of several polymers are displayed in Fig. 1 and 2. For the monomer pair 12, alkene protons of the diallyl amine part and maleate motif appeared at 8 5.5–6 ppm and 6.08 ppm, respectively (Fig. 1a), while the corresponding carbons are displayed at 8 126.4 (═CH), 127.2 (2C,═CH₂), and 135.1 (CH═CH) [Fig. 2a]. The low molar masses [as suggested by low viscosity values] and the absence of spectral signal for residual alkene protons or carbons of the polymers 9, 10 and 13 are indicative of degradative chain transfer³³ involving allylic hydrogens or a termination reaction by coupling.³⁴ The compact coil³⁵ conformation of MA-copolymer (+–) 13 is reflected in the broadened 1H as well as 1³ C NMR spectra (Fig. 1d and 2d), whereas the spectral signals are found to be sharp for homopolymer 9 or SO₂-copolymer 10 [Scheme 2] (Fig. 1b or 1c). The incorporation of MA in (+–) 13 is confirmed by the presence of a broad signal around 8 180 ppm (Fig. 2d). Elemental analysis and the spectral data confirmed the formation of the alternate copolymer because both the reactivity ratios r amat and r sma, are expected to be close to zero.¹⁰,³¹ Integration of the relevant carbon signals⁵⁵,³⁶ revealed a 3 : 1 cis/trans ratio of the ring substituents at Cb,b (Scheme 2).

3.4 TGA and viscosity behaviors PA (+–) 13

TGA plot for a PA 13 (dried under vacuum at 55 °C for 6 h) revealed the weight losses at various temperature ranges (Fig. 3a). The presence of adjacent CO₂H groups would lead as the formation of anhydride motifs with the loss of water as reflected by an 8.3% weight loss up to 200 °C. In fact, a loss of 1 molecule of water per repeating unit is calculated to be 7.9%. In the 200–380 °C range, maleic anhydride is itself released from the polymer backbone thereby accounting for the loss of ≈41.2% as compared to a calculated value of 46.9%.²⁰,³⁰,³⁷ A 48% loss in the 380–800 °C range is attributed to the removal of the amine units.

The viscosities of PA (+–) 13 are presented in Fig. 3b. The increase in viscosity with the increasing salt concentrations demonstrates the antipolyelectrolytic³⁸ nature of the poly-ampholyte [cf. Fig. 3b(i–iv)]. The ampholytic dipole is not perfectly electroneutral, rather it has a residual negative charge on CO₂⁻ since Na⁺ cannot effectively neutralize it as compared to the greater

RSC Adv., 2018, 8, 38891–38902 | 38897
shielding of $N^+$ by $\text{Cl}^-$. The magnitude of the excess negative charge, hence the viscosity, increases with salt concentrations.

PA (+−) 13 becomes a cationic polyelectrolyte 19 by protonation of $\text{CO}_2^-$ and as such its viscosity becomes higher in 0.1 M HCl because of repulsion among positive charges (Fig. 3b-v) (Scheme 3). The neutralization of 13 with one or two equivalents of NaOH leads to polyampholyte/anion (+−) 20 and poly-dianion (−) 21, the greater charge imbalance in the latter makes it more viscous (Fig. 3b-vi and vii).

Strong interactions of materials of GPC columns with functional groups like amine and $\text{CO}_2^-$ prevented the determination of molar masses of the polymers like 13. Similar observation was reported earlier. Purification by extensive dialysis with membrane of MWCO of 6000–8000 daltons indicates the products as true polymers not oligomers. The use of higher initiator dose along with degradative chain transfer termination process led to PA 13, having low molar mass as indicated by its lower $[\eta]$ value.

The intrinsic viscosities of the synthesized polymers 4a, 4b, 6, 9, 10, 13, 14, 16–18 are reported in the Tables 1–3. Since the MA incorporation is very minimal, 4a, 4b and 6 with the value of $y = 0$ resembled the copolymers 4a, 4b and 6 ($y = 0$) whose molar mass and $[\eta]$ are amply described. Similarly, polymers 17a, b which are similar to 18a, b ($y = 0$) and 16a have been extensively characterized in terms of viscosity and molar mass.

### 3.5 Basicity constant

As outlined in Scheme 3, the protonation constant $K$ of three basic centers in (−) 21 are calculated using eqn (3) where $\log K' = \text{pH at } a \ (\text{degree of protonation}) = 0.5$. The variation from the true basicity constant depends on the value of $n$ which equals 1 for small molecules. The values of $'n'$ and $\log K'$ were extracted from the slope and intercept of the pH vs. $\log([1 - a]/a)$ straight-line plot. The respective $\log K_1$, $\log K_2$ and $\log K_3$ were...
determined to be 10.1, 5.59 and 2.62, with the corresponding \( n_1 \), \( n_2 \) and \( n_3 \) values of 1.15, 2.19 and 0.48 (Table S1†).

All the \( n \) values, especially \( n_2 \) and \( n_3 \), are reflective of the "apparent" nature of the \( K_i \)s which changes with the \( \alpha \) as shown in Fig. 3c. The \( n \) value reflects a measure of the poly-electrolyte index. There are significant decrease and increase of \( \log K_2 \) and \( \log K_3 \), respectively, with increasing \( \alpha \), while the \( \log K_1 \) remains almost constant since the associated \( n \) value of 1.15 is not far from 1.

With increasing \( \alpha \), the equilibrium: \([\text{ZH}^{+\text{+}}] + \text{H}^+ \rightleftharpoons [\text{Z}^{2+}]\) is shifted to the right thereby decreasing \( \log K_3 \) as a consequence of decreasing negative charge density that

---

**Fig. 2** 13C NMR spectrum of (a) 12, (b) 9, (c) 10, (d) 13, and (e) 4a in D2O.
encourages protonation. This is in contrast to the increase of 
\[ \log K_{i} / C_{14} \] involving \( (ZH_{2}^{+} \ + c^{-} \ ^{13} + H^{+} ! (ZH_{3}^{+} \ + c^{-}) ^{19} \], whereby 
protonation of a repeating unit also decreases the overall 
negative charges of the polymer chain. The \( n \) values > or < 1 are 
caused by entropy effects. With each protonation, 
a repeating unit (RU) in ampholytic/anionic \( (ZH^{+} c^{-}) ^{20} \) 
collapses into an ampholytic RU of \( (ZH_{2}^{+} \ + c^{-}) ^{13} \). Ampholytic/ 
anionic \( (ZH^{+} c^{-}) ^{20} \) having excess negative charges is more 
hydrated than PA \( (+ c^{-}) ^{13} \) as supported by the higher viscosity 
value of the former \( (cf. \ Fig. 3b-vi vs. 3b-ii) \). The protonation of 
a RU leads to an entropically favourable release of water of 
hydration. For \( (ZH^{+} c^{-}) ^{20} \), as the \( \alpha \) increases, the average 
number of water molecules per RU in a polymer chain decreases 
which leads to a decrease in the magnitude of the positive 
entropy changes. Since the exothermic \( \Delta H^{\circ} \) is independent of \( \alpha \), 
the \( \Delta G^{\circ} \), hence \( K_{i} \) decreases with the increasing \( \alpha \).44

For the protonation of \( (ZH_{4}^{+} \ + c^{-}) ^{13} \) to \( (ZH_{3}^{+}) ^{19} \) (Scheme 3), 
the latter is more hydrated thus having expanded polymer chain 
as evinced by its greater viscosity value \( (cf. \ Fig. 3b-v vs. 3b-ii) \). The more exposed RU makes the neutralization process easier 
with the increasing \( \alpha \) \( (Fig. 3c, i = 3) \). With increasing \( \alpha \), increasing imbalance in favour of positive charge also increases 
the degree of hydration which leads to greater entropy changes 
because of release of a greater number of molecules during 
progressive protonation.

### 3.6 Scale inhibition study

In a Reverse Osmosis (RO) process, feed water is converted to 
product water and rejects brine, in which supersaturation of 
dissolved salts, like \( \text{CaSO}_{4} \) and \( \text{CaCO}_{3} \), may lead to precipitation 
which reduces the efficacy of the membrane separation process.

The percent scaling inhibition (PSI) is calculated using eqn 
(4):

\[
\text{PSI} = \frac{[\text{Ca}^{2+}]_{\text{inhibited}}(i) - [\text{Ca}^{2+}]_{\text{blank}}(i)}{[\text{Ca}^{2+}]_{\text{inhibited}}(i)} \times 100
\]

where \([\text{Ca}^{2+}]\) concentrations are used at time zero and \( t \). The 
inhibited and blank are used to describe the presence and 
absence of the antiscalant.

The concentration of \( \text{Ca}^{2+} \) and \( \text{SO}_{4}^{2-} \), present in the reject 
brine of a RO plant, was described as \( \text{1-CB} \) (concentrated 
brine). The scaling behavior in the presence of PA \( 13 \) was carried out 
in a supersaturated solution of \( \text{CaSO}_{4} \) comprising \( 3\text{-CB} \)

*“Three times the concentration of Ca^{2+} and SO_4^{2−} found in the concentrated brine of an RO plant.”

concentration of Ca^{2+} (2600 ppm) and SO_4^{2−} (6300 ppm) by conductivity measurements. A sudden drop in the conductivity indicates the onset of CaSO_4 scaling (Fig. 3d).

It is indeed satisfying that in the presence of 5 and 20 ppm 13, a 100% scale inhibition was registered for about 50 and 500 min, respectively (Table 4). Since the reject brine usually has a residence time of ≈30 min in the osmosis chamber, the current antiscalant may thus be very effective in inhibiting CaSO_4 scaling. As shown in Fig. 3d, the onset of precipitation occurs after an induction period; an accelerated growth of CaSO_4 crystals is induced by a sudden drop in conductivity. For a duration of 700 min, 20 ppm PA 13 did not show any induction time. The crystal growth starts after nucleation process, which is interfered with the complexation of the metal ions by the chelating ligands of the antiscalant.48,49 The gypsum scale, *i.e.*, CaSO_4 in mineral form, occurs during several processes involving production of water.50 PA 13 is found to be remarkably efficient in preventing scale formation, and as such it has the ability to mitigate the membrane fouling in RO plants.

4. Conclusions

Several diallylamine derivatives 1a, b, 5 and 7 as well as quaternary diallyldialkylammonium chlorides 15a, b has been terpolymerized with MA and SO_2 using APS initiator or UV light at a λ of 365 nm in an attempt to obtain amine (salt)–MA–SO_2 terpolymer. In contrast to reported literature, only 1–2 mol% of MA was incorporated into the polymer chain mainly consisting of amine (salt)–SO_2 copolymers. The non-incorporation of MA is attributed to the far greater rate of propagation of amine (salt)–SO_2 than either amine (salt)–MA or MA–SO_2 under the polymerization conditions. The reactivity ratios of both monomers in the amine (salt)–MA and MA–SO_2 pairs are ≈0; however, in a three-monomer system: amine (salt)–MA–SO_2, the very slow reactivity of MA does not allow its incorporation into terpolymer chain to any meaningful extent.

The 1c–MA copolymer PA 13 has been synthesized in excellent yield with an anticipation that it could be a potential antiscalant. Under pH-induced changes, stimuli-responsive polyampholyte 13 was transformed to cationic 19, polyampholyte-anionic 20, and dianionic polyelectrolyte 21 to examine their viscosity. The viscosity values of 13 in the presence of salt NaCl confirmed its antipolyelectrolyte behaviour. The log \( K \) (i.e. \( pK_a \)) of two carboxylic acid groups and NH\(^+\) in 13 has been determined to be 2.62, 5.59, and 10.1, respectively. PA 13 was evaluated as an antiscalant for potential application in reverse osmosis (RO) plants. At concentrations of 5 and 20 ppm, it demonstrated remarkable efficiency of ≈100% for CaSO_4 scale inhibition from its supersaturated solution for 50 and 500 min, respectively. Since an antiscalant should be effective for the duration of brine’s residence time (≈30 min) in the osmosis chamber, the synthesis of PA 13 in excellent yields from cheap starting materials and its very impressive performance may accord it a prestigious place among many an environment-friendly phosphate-free antiscalant. Note that polyphosphate additives used for controlling scale formation, when discharged in the sea have deleterious influence over the marine biota picture.51
