Carbocation catalysed ring closing aldehyde-olefin metathesis†

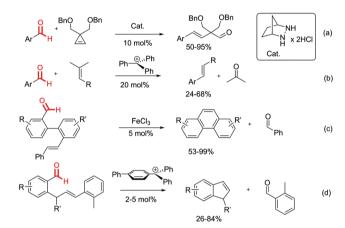

Shengiun Ni and Johan Franzén *

A highly efficient aldehyde-olefin metathesis catalysed by the carbocation, 4-phenylphenyl-diphenylmethylium ion, has been developed. This protocol is characterized by high yields, low catalyst loading (down to 2 mol%), good functional group compatibility and mild reaction conditions.

In contradiction to the well established transition metal catalysed alkene-alkene metathesis,1 the direct catalytic carbonyl-olefin metathesis is vastly underdeveloped despite its great potential with respect to atom economy and substrate scope. In the forefront of current research, a series of successful iron(III)catalysed ring closing ketone-olefin metathesis strategies have been reported.²⁻⁶ However, the catalytic aldehyde-olefin metathesis still remains elusive. As one of the few exceptions, Lambert et al. reported the first aldehyde-olefin metathesis, where they showed that a bicyclic hydrazine derivate could catalyse the ring opening metathesis of cyclopropene derivatives and aldehydes (Scheme 1, equiv. (a)).8 Unfortunately, this work was limited to cyclopropene derivatives as the olefinic component. Our group reported intermolecular aldehyde-olefin metathesis by carbocation catalysis as an extension of the earlier report by Bickelhaupt (Scheme 1, equiv. (b)). 9-11 Although an important proof of concept, from the synthetic point of view, this protocol suffered from high catalyst loading and a rather limited substrate scope. The main problem associated with aldehydeolefin metathesis is mainly due to the decomposition of both the starting materials and the products in the presence of the Lewis acid catalysts required for the reaction. Schindler et al. reported a few specific examples of intramolecular aldehydeolefin metathesis in the formation of highly stable polycyclic aromatic compounds (Scheme 1, equiv. (c)).3b

Here we show that 4-phenylphenyl-diphenylmethylium tetrafluoroborate efficiently catalyses the intramolecular aldehydeolefin metathesis of enals under mild reaction conditions and

low catalyst loading with high yields (Scheme 1, equiv. (d)). It is shown that the substituents on the olefin moiety as well as the carbocation Lewis acidity are of crucial importance for minimizing starting material and product decomposition.

The general mechanism for the Lewis acid mediated metathesis is proposed to involve Lewis acid (LA) induced LUMO activation of enal A through initial formation of oxonium ion B (Scheme 2). The latter is now activated toward nucleophilic attack from the pendant alkene moiety resulting in the formation of oxetane C. The formation of oxetane C can occur either through a stepwise [2+2] mechanism involving a carbocationic

Scheme 3 Comparison of aldehyde-olefin and ketone-olefin metatheses.

intermediate, or through a concerted [2+2] cycloaddition. Recent mechanistic studies by Schindler et al. for FeCl3 catalysed ketone-olefin metathesis show strong support for a Lewis acid induced concerted, asynchronous [2+2]-cycloaddition.3c A subsequent fragmentation of oxetane C, either a stepwise or concerted retro-[2+2] cycloaddition, leads to the formation of the cycloalkene adduct D and the carbonyl by-product E.

In line with our previous work^{9,11a-e} and inspired by the elegant work of Schindler³ and Li, 4 we sought to overcome the difficulties associated with the catalytic aldehyde-olefin metathesis and turned our attention towards the trityl ion catalysed ring closing metathesis of enal 1. After extensive optimization, the best yield of indene 2a was 60% after full conversion of 1a in only 5 minutes (Scheme 3). This indicates that enal 1 decomposes or undergoes side reactions in the presence of TrBF4. Furthermore, as outlined in the mechanistic proposal of the carbonyl-olefin metathesis (see Scheme 2), the metathesis adduct D and a new carbonyl compound E are formed in a 1:1 ratio. Thus, a comparison of the yield of 2a with the yield of the formed acetone (60% and 76%, respectively) indicates that product 2a decomposes under these reaction conditions, most likely through Lewis acid initiated polymerization. In comparison, the metathesis of the corresponding ketone 3 under the same reaction conditions gave a very high yield, almost the same as that of 4 and acetone, indicating minor decomposition/ side reactions of starting material 1b and negligible trityl ion induced decomposition of methyl-indene 4 (Scheme 3).

Inspired by Li's work4 we instead investigated the trityl ion catalysed ring closing metathesis of enals. Gratifyingly, indene 2a and benzaldehyde 6a were obtained in 71% and 86% yields, respectively (Table 1, entry 1). Surprisingly, FeCl₃, which was successfully used for intramolecular ketone-olefin metathesis both by Schindler and Li, 3,4 rapidly consumed enal 5 without any observable formation of indene 2a (Table 1, entry 2). However, the formation of benzaldehyde 6a in 74% yield shows that the metathesis do occur although indene 2a rapidly decomposes in the presence of FeCl₃. The same outcome was observed for InCl₃, BF3·Et2O and HBF4·Et2O that gave benzaldehyde 6a in high yields and with low or no observable formation of indene 2a (Table 1, entries 3-5). AlCl₃ was the least efficient catalyst with only 36% conversion and 3% yield (Table 1, entry 6).12

In order to gain further insight into the metathesis process, in terms of reactivity and Lewis acid induced decomposition, we turned our attention to the styryl moiety. Decreasing the electron density/nucleophilicity through an electron withdrawing para-nitro group (enal 7) completely stopped both enal

 $[^]a$ Reaction conditions: TrBF $_4$ (10 mol%) was added to 7–10 in DCM (0.01 M) for the indicated time at room temperature. b Yields were determined by ¹H NMR spectroscopy. ^c 5 mol% of Cat C was used.

decomposition and metathesis and only starting materials could be recovered (Table 2, entry 1). In contrast, increasing the electron density/nucleophilicity of the alkene by introducing an electron donating para-methoxy-group greatly accelerated the decomposition of enal 8 in the presence of TrBF4, enabling full conversion in only 5 minutes with a low yield of indene 2a (Table 2, entry 2). Additional tuning of the electronic properties of the alkene moiety revealed that the weak electron donating groups o-methyl 9a and p-methyl 10 shorten the reaction time, leading to a somewhat reduced product decomposition and only a minor increased enal decomposition (Table 2, entries 3 and 4). Among the latter, o-methyl substituted enal 9a was the most efficient, affording indene 2a in 75% yield (Table 2, entry 3). 13

After identifying the o-tolyl-group in enal 9a as the best alkene-leaving group, we investigated the influence of carbocation Lewis acidity on the aldehyde-olefin metathesis. The trityl ChemComm Communication

ion constitutes a rather unique mode of carbon-centered Lewis acidity with extensive possibilities for relatively easy tuning through variation of the electronic properties of the surrounding aromatic groups. 11a-e,14 The trityl ions Cat A-C were screened as catalysts for the metathesis of enal 9a. The mono-methoxy substituted trityl ion, Cat A, is the least Lewis acidic carbocation screened, due to the strong electron donating properties of the p-methoxy-phenyl group to the carbocationic center. Unfortunately, the lower Lewis acidity of Cat A resulted in a drastically prolonged reaction time and low yield of indene 2a and did not prevent starting material/product decomposition (Table 2, entry 5). The mono-methyl substituted trityl ion, Cat B, is a considerably stronger Lewis acid compared to Cat A although it is less Lewis acidic compared to TrBF4 and gave full conversion after 4 h (Table 2, entry 6). Interestingly, despite the increased reaction time, the yield was virtually the same as for TrBF₄, indicating that product decomposition was considerably slower with Cat B (Table 2, entry 6). However, after extensive screening, we found that with the mono-p-phenyl substituted trityl ion, Cat C, the yield of indene 2a could be increased up to 80% within 3 h (Table 2, entry 7). Notably, reducing the catalyst loading to only 5 mol% prolonged the reaction time to 8 h without any loss in the yield (Table 2, entry 8). Thus, the p-phenyl substituted trityl ion, Cat C, almost completely diminished product decomposition, giving essentially the same yields of metathesis adduct 2a and 2-methylbenzaldehyde 6.

With these optimal conditions in hand (Cat C (5 mol%), DCM, RT), the aldehyde-olefin metathesis of enal 9a gave indene 2a in 81% isolated yield (Table 3, entry 1). Introducing a methyl-substituent in the 5-position of enal 9b gave the corresponding 7-methyl-indene **2b** in 71% yield (Table 3, entry 2). In contrast, the 3-methyl-group in enal 9c greatly accelerated the metathesis and afforded 7-methyl-indene 2c in 78% yield within 30 minutes of reaction time (Table 3, entry 3). The increased reactivity is most likely a result of 1,3-allylic strain induced by the 3-methyl-group that locks the conformation with the olefin side chain in closer proximity to the aldehyde moiety.

^a Reaction conditions: Cat C (5 mol%) was added to 9 in DCM (0.01 M) for the indicated time at room temperature. b Isolated yield.

The 5-methoxy-substituted enal 9d also had an accelerating effect on the metathesis and gave 5-methoxy-indene 2d in 68% isolated yield (Table 3, entry 4). In contrast, the 4-methyl-group in enal 9e and the 2-benzyloxy-group in 9f gave the corresponding indenes 2e and 2f in low yields (Table 3, entries 5 and 6). This is most likely due to the increased product decomposition as a result of the higher reactivity of 6-methyl-indene 2e and 4-benzyloxy-indene 2f caused by the electron donating properties of the methyl- and benzyloxy-groups in the para- and ortho-positions, respectively, to the indene double bond. Different halogenated enals were also screened and fluorinated enals 9g-i gave indenes 2g-i in good yields. However, the 5-chlorosubstituent in enal 9i had a negative effect on the metathesis and 5-chloro-indene 2j was isolated in 45% yield.

We next evaluated functionalization at the benzylic position of enals 11 that would allow for easy access to 1-functionalized indenes 12 (Table 4). To our delight, functionalization at this position had a remarkable effect on the reactivity and for the Cat C catalysed metathesis of enals 11a-h, the catalyst loading could be reduced down to 2.0 mol% without any loss in the efficiency. Under these conditions, the corresponding products **12a-h** were isolated in 78–84% yields within less then one hour. This drastic increase in the reactivity is most likely due to the Thorpe-Ingold effect favouring cyclization. However, the 3-benzyloxypropyl functionalized enal 11i reacted considerably slower and required 5 mol% catalyst loading to give indene 12i in 80% yield. The terminal alkene moiety in enal 11j had a negative influence on the metathesis with an increased reaction time and side reactions to give 12j in only 37% yield.

In conclusion, we have developed a direct organocatalytic aldehyde-olefin ring closing metathesis. The reaction is operationally simple and enables direct coupling of aldehydes and pendant olefins in the presence of the easily available 4-phenylphenyl-diphenylmethylium ion as the Lewis acid catalyst. The catalyst loadings can be reduced as low as 2 mol% and the

products are isolated in good yields, often in a very clean and selective manner. With the developed procedure, a variety of functionalized indene derivatives could be easily prepared. This protocol represents a rare example of a catalytic aldehydeolefin metathesis and efforts to extend this process to a broader array of substrates are currently on going in our laboratory. These results will be reported in due course.
