On verdigris, part II: synthesis of the 2-1-5 phase, $\text{Cu}_3(\text{CH}_3\text{COO})_4(\text{OH})_2 \cdot 5\text{H}_2\text{O}$, by long-term crystallisation from aqueous solution at room temperature†‡

Sebastian Bette, *^a Reinhard K. Kremer, ^a Gerhard Eggert ^b and Robert E. Dinnebier ^a

Long-term crystallisation from aqueous copper(II)-acetate solution after the addition of ammonia at 25 °C led to the formation of a hitherto poorly characterised phase in the verdigris pigment system $\text{Cu}(\text{CH}_3\text{COO})_2 \cdot \text{Cu}(\text{OH})_2 \cdot \text{H}_2\text{O}$. Laboratory X-ray powder diffraction (XRPD) was successfully employed to solve the crystal structure. The structure solution reveals a phase composition of the $\text{Cu}_3(\text{CH}_3\text{COO})_4(\text{OH})_2 \cdot 5\text{H}_2\text{O} \equiv 2\text{-}1\text{-}5$ phase, which was also confirmed by thermal analysis. The 2-1-5 phase crystallises in space group $P2_1/c$ (14) with lattice parameters of $a = 12.4835(2)$ Å, $b = 14.4246(2)$ Å, $c = 10.7333(1)$ Å and $\beta = 102.871(1)^\circ$. The crystal structure consists of $\text{Cu}_2(\text{CH}_3\text{COO})_2(\text{CH}_3\text{COO})_{1/2}(\text{OH})_{4/3} \text{H}_2\text{O}^{1/6+}$ dimers that are interconnected by $\text{Cu}(\text{CH}_3\text{COO})(\text{CH}_3\text{COO})_{1/2}(\text{OH})_{2/3}^{1/6-}$ squares forming chains running in the c -direction. Non-coordinating hydrate water molecules are intercalated inbetween the chains and mediate the inter-chain interaction. IR and Raman spectroscopy techniques were also employed to confirm selected aspects of the determined crystal structure. The magnetic properties of the 2-1-5 phase decompose into two independent subsystems: a strongly antiferromagnetically spin exchange coupled magnetic Cu–Cu dimer and a significantly weaker coupled Cu monomer. The light blue colour of the sample originates from a reflectance maximum at 488 nm and significantly differs from the known verdigris phases. An investigation of several historic verdigris pigment samples revealed that this phase occurs both as a minor and a major component. Hence, our reference data for the title compound will help to improve the understanding of the multiphase mixtures occurring in historic verdigris samples.

Introduction

Pigments have been used by mankind since the early Stone Age. At the beginning, only naturally occurring pigments, *i.e.* minerals, were used. Much later, pigments were also produced artificially. One of the oldest synthetic pigments is “verdigris”, which is a collective term for green and blue copper based painting pigments. Until the 19th century, verdigris pigments were frequently used for the artistic scope (Fig. 1) and often produced by intentional corrosion of copper using carboxylic acids, mainly acetic acid (from vinegar).¹ The pigment production also included purification and recrystallisation

procedures. Numerous “recipes” for all production steps have been reported using different ingredients and applying different conditions in terms of temperature, time, *etc.* Hence, a great variety of verdigris pigments differing in colour, resistivity against degradation and chemical composition exist. In addition to their use as pigments, verdigris phases were used for other applications, *e.g.* medical purposes, as well.²

Verdigris is classified into two categories: neutral or sometimes distilled verdigris referring to $\text{Cu}(\text{CH}_3\text{COO})_2 \cdot \text{H}_2\text{O}$ or $\text{Cu}(\text{CH}_3\text{COO})_2$ and basic verdigris. The latter category refers to a group of copper(II)-acetate hydroxide salts, also known as “basic copper(II)-acetates”, which are distinguished and denoted according to their chemical composition: $x\text{Cu}(\text{CH}_3\text{COO})_2 \cdot y\text{Cu}(\text{OH})_2 \cdot z\text{H}_2\text{O} \equiv x - y - z$ phase. Numerous synthesis attempts^{1,3–6} based on ancient recipes for verdigris revealed the existence of at least five distinct phases: 2-1-5, 1-1-5, 1-4-3, 1-2-0 and 1-3-2. Only the 1-3-2 phase^{1,4,5,7–14} and very recently the 1-2-0 phase¹⁵ were characterised in detail, as the purity of the obtained basic copper acetates could not be proved unambiguously because the phase characterisation led

to contradictory results. In addition, ancient recipes, in particular the intentional corrosion of copper, were proved to lead to complex multiphase mixtures^{14,16,17} comprising components which could not be identified due to a lack of reliable reference data. Historic verdigris samples are even more complex as most of them are multiphase mixtures, as well as they are usually already affected by degradation processes.¹⁸ This emphasizes the need for reliable reference data for the pure $x - y - z$ phases which can serve as a basis for phase identification, e.g. by vibrational spectroscopy or quantification by X-ray powder diffraction (XRPD).

Besides their relevance as pigments, copper carboxylates attract broad scientific interest as materials for anion exchangers,^{10,11,19,20} for heterogeneous catalysis¹¹ and due to their tuneable magnetic properties.^{12,13,21–23} These investigations however were focused mainly on the 1-3-2 phase. The crystal structure of the 1-3-2 phase was solved both from powder⁷ and single crystal⁸ X-ray diffraction. Crystalline powders of the 1-3-2 phase were obtained by adding NaOH⁷ or NH_{3(aq)}^{4,5} to concentrated Cu(CH₃COO)₂ solution⁸ at 60 °C. Single crystals were grown by refluxing a 0.1 M Cu(CH₃COO)₂ solution at 60 °C for 60 h without stirring⁸ or by crystallisation from gel.²⁵ The 1-3-2 phase can be converted into the 1-2-0 phase by ageing in concentrated Cu(CH₃COO)₂ solution at 60 °C.^{4,15} Reported synthesis routes that lead to the direct formation of the 1-2-0 phase,^{5,6} as well as the synthesis procedures for the 2-1-5, 1-1-5 and 1-4-3 phases, were found to be irreproducible.¹⁵

In order to extend the knowledge of the formation, stability, properties, and crystal structures of verdigris phases, we performed long-term crystallisation experiments. These were carried out at room temperature since lower temperatures usually lead to phases with higher water contents although the formation, transformation and crystallisation of hydroxide salts can take years.^{26,27} This procedure led to the successful synthesis of the 2-1-5 phase. The thermal behaviour, as well as the spectral and magnetic properties of this phase, was investigated and the crystal structure was solved from laboratory XRPD data.

Experimental section

Long-term crystallisation approaches

The investigations of the long term crystallisation of verdigris phases were carried out by using 3 approaches. The synthesis approaches are summarised in a scheme in Fig. S1 in the ESI.†

Approach I

In *approach I*, 5.9 g (0.030 mol) Cu(CH₃COO)₂·H₂O (Merck, p.A.) were dissolved in 51.9 g of deionised water that had been boiled several minutes before in order to remove dissolved carbonate, at 70 °C yielding a 0.57 m (≡ moles Cu(CH₃COO)₂ per kg of H₂O) solution. During stirring, 1.5 mL of 24 wt% NH_{3(aq)} (≡ 0.019 mol NH₃) were added at 70 °C. After 4 minutes, the addition was completed and the turquoise precipitate that was formed immediately was filtered off after two additional minutes of stirring. The filtrate was slowly cooled down to room temperature. After 4 months, the formation of a light blue precipitate was observed. The precipitate was finally filtered off after 14 months. In order to remove the adhered mother liquor, the solid was suspended in cold ($T < 4$ °C), deionised water, twice, and once in cold ($T < 4$ °C) ethanol. Drying was carried out for 48 h at room temperature. Only a small amount of the solid, approximately 20 mg, was obtained.

Approach II + III

In *approach II* and *III*, 11.8 g (0.060 mol) Cu(CH₃COO)₂·H₂O were dissolved in 88.3 g of deionised water at 70 °C yielding a 0.67 m copper(II)-acetate solution. During stirring, 3.0 mL of 24 wt% NH_{3(aq)} (≡ 0.039 mol NH₃) were added at 70 °C. After 6 minutes, the addition was completed and stirring was continued for 2 minutes. A turquoise precipitate formed immediately. The suspensions were stored for 7 days at 60 °C. During this time, the turquoise solid changed its colour into a deep blue. In *approach II*, the solid was filtered off and the filtrate was aged further for 12 months at room temperature. In *approach III*, the suspension was cooled down to room temperature and aged for 12 months, as well. During ageing, a light blue solid was formed in *approach II* and the solid in *approach III* turned slowly into a light blue. After ageing, the solids were filtered off and the removal of the mother liquor and drying was conducted as described above.

Phase characterisation

SEM images of the purified and dried solids were obtained with a MERLIN scanning electron microscope (Zeiss) (5.0 kV accelerating voltage, SE-detector), after coating the sample with iridium. μ -Raman spectroscopy was carried out using a Renishaw inVia Raman spectrometer with a Leica DMLM microscope and a RenCam CCD detector. The spectrometer was equipped with a He–Ne laser operating at 632.8 nm, with power maintained below 400 μ W on the sample surface. Thermal analysis was carried out using a STA 449 F5-Jupiter (Netzsch) device for TG-measurements. 12.6 mg of the sample were placed in an Al₂O₃ crucible and heated up from 30 °C to 500 °C with a heating rate of 2 K min⁻¹ in a 50 mL min⁻¹ Ar-stream. The magnetic measurement of a powder sample enclosed in a gel capsule was carried out in the temperature range from 1.8 K to 300 K in a DC mode using a SQUID magnetometer (MPMS XL, Quantum Design) at 0.1 T, 1.0 T and 7.0 T. XRPD patterns for phase identification were recorded at room temperature on a laboratory powder diffractometer in Debye–Scherrer geometry (Stadi P-Diffraktometer (Stoe), Cu-K α_1 radiation from a primary Ge(111)-Johann-type monochromator, and a Mythen 1 K detector (Dectris)). The samples were sealed in 0.5 mm diameter borosilicate glass capillaries (Hilgenberg glass no. 0140), which were spun during the measurements. Each pattern was measured in a 2θ range from 5.0° to 70° applying a total scan time of 5 h. The XRPD pattern for the crystal structure solution was recorded using the same device applying a scan range from 5.0° to 100° 2θ and a total scan time of 20 h. Temperature dependent *in situ* X-ray diffraction experiments were performed on a D8-Advance diffractometer (Bruker, Cu-K α_1 radiation from a primary Ge(220)-Johannson-type monochromator and a Lynx Eye position sensitive detector (Bruker)) in Debye–Scherrer geometry using a water cooled furnace (mri capillary heater, (25–1000) °C) for heating the capillary. The sample was sealed in a 0.5 mm diameter quartz glass capillary (Hilgenberg), which was spun during the measurement. The patterns were measured with a scan range of 5.0 to 40.0° 2θ , employing a step size of 0.005 and a total scan time of 4 h. A delay time of 30 min was applied before each measurement to ensure thermal equilibration.

Crystal structure solution

The programme TOPAS 6.0²⁸ was used to determine and refine the crystal structure of the 2-1-5 phase. The indexing of the pattern was carried out by an iterative use of singular value decomposition (LSI)²⁹ leading to a primitive monoclinic unit cell with lattice parameters given in the ESI (Table S1†). The observed systematic reflection extinction pointed to $P2_1/c$ (14) as the most probable space group. The peak profile and the precise lattice parameters were determined by LeBail³⁰ fits applying the fundamental parameter approach of TOPAS.³¹ The background was modeled by employing Chebychev polynomials of the 6th order. The refinement converged quickly.

Considering the unit cell volume, the site multiplicities in space group $P2_1/c$ (14) and the packing densities of the related

copper(II)-acetate-hydroxide hydrates,^{7,8,15} the number of formula units per unit cell, Z , was estimated as 4. The method of Charge Flipping³² with histogram matching³³ supported by inclusion of the tangent formula³⁴ was used to determine the positions of the copper ions. By applying the global optimisation method of simulated annealing (SA) in the real space as it is implemented in TOPAS,³⁵ the positions of the acetate and hydroxide ions and water molecules were determined. Rigid bodies for the acetate ions were defined in z -matrix notation and translated and rotated freely through the unit cell. Atoms located on identical positions were identified by using a merging radius of 0.7 Å.³⁶ After a few hours, the positions of all atoms were found. The procedure was carried out several times and as a result the simulated annealing process always yielded identical structural models that were independent from the starting parameters, *i.e.* the number of atoms that were initially put into the unit cell. For the final Rietveld refinement,³⁷ all profile and lattice parameters were released iteratively and positions of the copper and oxygen (hydroxide ions and water molecules) atoms were subjected to free unconstrained refinement. The bond lengths and angles of the rigid bodies of the acetate ions were refined, restraining them to chemically reasonable values. Hydrogen sites were omitted due to the limits of the powder diffraction method. The final agreement factors are listed in Table S1,† the atomic coordinates and selected bond distances are given in Tables S2 and S3,† the fit of the whole powder pattern is shown in Fig. S2 in the ESI.† The crystallographic data are deposited at the CCDC, deposit number: 1840957.†

Results and discussion

Phase identification and morphology

Long term crystallisation experiments were performed from clear solution after the filtration of the initially formed 1-3-2 phase (*approach I*), the subsequently formed 1-2-0 phase (*approach II*) and from a suspension of the 1-2-0 phase (*approach III*) at room temperature for at least one year (ESI Fig. S1†). All long-term crystallisation approaches led to the formation of light blue powders (ESI, Fig. S1†). *Approach I* results in the formation of a very small amount of solid (approx. 20 mg), whereas *approach II* and *III* yielded more materials (100 mg–200 mg). The diffraction patterns of the obtained solids differ (Fig. 2c–e).

The diffraction pattern of the solid obtained by *approach I* (Fig. 2c) which was identified to be the 2-1-5 phase by the crystal structure solution (see below) can be clearly distinguished from the pattern of the 1-2-0 phase (a). Due to the identical position of the basal reflections of the 1-3-2 and 2-1-5 phases at *ca.* 9.6° 2θ ($\equiv d = 9.3$ Å), the diffraction patterns of these verdigris phases (Fig. 2b and c) exhibit strong similarities. The indexing of the latter phase, however, leads to a different space group and different lattice parameters (inset). The broad hump in the background of the XRPD pattern indicates some amount of an amorphous phase. The diffraction pattern of the solid obtained by *approach II* (Fig. 2d) exhibits

Fig. 2 XRPD patterns of known verdigris phases: (a) 1-2-0 phase and (b) 1-3-2 phase (including selected reflection indices) and patterns of the solids obtained by long-term crystallisation: (c) approach I \equiv 2-1-5 phase (including selected reflection indices and refined lattice parameters), (d) approach II \equiv 2-1-5 phase + unknown phase (indicated by ∇) and (e) approach III \equiv heavily disordered phase.

both broad and sharp reflections, indicating a polyphase mixture. The sharp reflections can be assigned to the 2-1-5 phase (indices) and the broad reflections (indicated by ∇) cannot be assigned to any known phase. Hence, a further unknown verdigris phase is apparent as a by-product. This indicates that the phase transformation is still ongoing in *approach II*. It cannot be concluded whether the 2-1-5 phase or the unknown poorly crystalline phase is metastable. In the diffraction pattern of the solid obtained by *approach III*, only one reflection corresponding to a d value of 10.3 Å is clearly visible (Fig. 2e). All other reflections are vastly broadened and exhibit a characteristic triangular peak shape that indicates a stacking fault disorder. The position of the basal reflection is identical to the corresponding reflection of the 1-2-0 phase (Fig. 2a) but also to the first two reflections of the crystalline by-product of approach II. This indicates that the latter phase is transformed into another copper(II)-acetate-hydroxide hydrate *via* a structurally disordered intermediate state. The process of phase transformation does not seem to be completed after more than one year.

The crystallites of the 2-1-5 phase exhibit a needle-like morphology (Fig. 3a). They can be clearly distinguished from plate-like crystals of the 1-3-2 phase (g) and the 1-2-0 phase (h). Higher magnification reveals that the needles of the 2-1-5 phase are polycrystalline aggregates of fibre-like crystals (b). Despite the XRPD analysis clearly showed that the solid obtained by *approach II* consists of two phases, the well crystalline 2-1-5 phase and the poor crystalline unknown phase, the SEM images show polycrystalline needle-like aggregates of fibre-like crystals, exclusively c and d. Therefore, the additional unknown phase exhibits a needle-like morphology, as well. The SEM image of the heavily disordered solid obtained by *approach III* shows aggregates of needle-like crystallites, as well (e and f). Compared to the solids obtained by approaches I and II, these aggregates are much broader and they exhibit some similarity to the rectangular plate-like crystals of the 1-2-0 phase that was intermediately apparent in *approach III*.

Fig. 3 SEM images of the solids obtained by long-term crystallisation (a + b) *approach I* \equiv 2-1-5 phase, (c + d) *approach II* \equiv 2-1-5 phase + unknown phase, (e + f) *approach III* \equiv heavily disordered phase and (g + h) of known verdigris phases: (g) 1-3-2 phase and (h) 1-2-0 phase.

Investigation of historic pigment samples

Due to the small yield and the long crystallisation time, it appears unlikely that the 2-1-5 phase is relevant for the understanding of historic verdigris samples. Surprisingly by an investigation on three historic pigment samples of the Medicinsk Historisk Museum obtained from the School of Conservation in Copenhagen, however, the presence of the 2-1-5 phase was confirmed.

In two of the historic samples which were labelled as “copper acetate”, the 2-1-5 phase was identified as a minor impurity (3.2 wt% and 6.0 wt%) (ESI, Fig. S3a and b†). One sample labelled as “basic copper acetate” with a 1-1-5 phase composition (Fig. 4a) was revealed to be a polyphase mixture (b). In the XRPD, most reflections could be assigned to copper(II)-acetate monohydrate (Fig. 4b, green pattern) and to the 2-1-5 phase (black pattern), the measured intensity at the position of the 011 reflection, however, is too high in relation to the 110 basal reflection. Hence, at this position, a second reflection attributed to another phase is apparent. In addition, at *ca.* $6.5^\circ 2\theta$, a broad reflection (indicated by \blacklozenge) is present that is neither attributed to the 2-1-5 phase nor to copper(II)-acetate monohydrate and to any other known verdigris phases or their degradation products. Hence, a third phase is apparent which can neither be identified nor be indexed due to a lack of unambiguously assignable reflections, yet. In the SEM images (Fig. 4c and d), elongated structures are visible but everything is covered by a solid of an indefinite shape. Copper(II)-acetate monohydrate is most likely crystallised from adherent solution during the drying process and therefore covers the verdigris particles.

As the 2-1-5 phase was identified to be a component of historic pigments, a more efficient synthesis route in terms of time and yield most likely exists.

Crystal structure description

In the crystal structure of the 2-1-5 phase, three crystallographically independent copper sites are apparent (Fig. 5a).

Fig. 5 Coordination spheres of the copper cations (a) and the acetate ions (b) in the crystal structure of the 2-1-5 phase, orange bonds indicate directly coordinating ligands, and interactions within the extended coordination sphere are indicated by grey dashed bonds.

Each cation site is coordinated by 4 oxygen atoms from hydroxide, water and acetate forming distorted squared planar coordination spheres (orange bonds) with Cu–O distances between 1.83 Å and 2.07 Å (ESI, Table S3†), which is in the expected range for this class of compounds.^{7,8,15} In addition, carboxylate related oxygen atoms are located in the extended coordination sphere (Fig. 5a, grey, dashed bonds) with Cu–O distances ranging from 2.29 Å to 2.41 Å resulting in squared pyramidal extended coordination spheres of Cu(1) and Cu(2) and in a Jahn–Teller-like distorted octahedra extended coordination sphere of Cu(3). The coordination polyhedra of Cu(1) and Cu(2) form corner-sharing dimers that are linked to an

Fig. 4 Investigation of a historic verdigris sample labelled as “Basisk Cupriacetat, $(\text{CH}_3\text{COO})_2\text{Cu Cu}(\text{OH})_2, 5 \text{ H}_2\text{O}$ ”, (a) photograph ©School of Conservation, Copenhagen, (b) XRPD pattern including assignment of the measured reflections, unassigned reflection are indicated by \blacklozenge , (c + d) SEM images of the sample.

edge-sharing Cu(3) unit. Bridging occurs *via* the O(1) and O(3) sites that are coordinated by 3 copper ions. Hence, these sites are most likely occupied by hydroxide ions. The O(2) site is apical and therefore most likely occupied by water.

There are also 4 independent acetate sites in the crystal structure of the 2-1-5 phase (Fig. 5b). The carboxylate oxygen atoms are always at apical positions in the coordination spheres of copper. Acetate (a) bridges Cu(2) and Cu(3) and therefore it acts as a *bidentate* and *bridging* ligand. In contrast, acetate (d) is a pure *monodentate* ligand in the coordination sphere of Cu(3). The oxygen site (1) of acetates (b) and (c) is part of the coordination sphere of Cu(2) and Cu(3), respectively. As the second carboxylate, oxygen (O(2b), O(2c)) are situated within the extended coordination sphere of Cu(3), these acetates obtain a *pseudo bidentate* and *pseudo bridging* character.

The $\text{Cu}_2(\text{CH}_3\text{COO})_2(\text{CH}_3\text{COO})_{1/2}(\text{OH})_{4/3}\text{H}_2\text{O}^{1/6+}$ dimers are connected by edge-sharing $\text{Cu}(\text{CH}_3\text{COO})(\text{CH}_3\text{COO})_{1/2}(\text{OH})_{2/3}^{1/6-}$ squares resulting in chains running in the *c*-direction with an alternating orientation of the dimers and the Cu(3)O₄ units as the most prominent structural motif of the 2-1-5 phase (Fig. 6a). Interactions between the chains are mediated by non-coordinated water molecules that occupy the O(4–7) sites (Fig. 7, grey dashed lines). The O–O distances range from 2.68 Å to 2.97 Å which indicate strong interactions between non-coordinated water molecules and hydroxide or acetate ions. Some of these interactions are most likely H-bonds but due to the limits of the XRPD method, no hydrogen positions could be determined. The thermal behaviour (see below) of the phase, however, shows that the non-coordinated water molecules are loosely bound.

The chains in the crystal structure of the 2-1-5 phase are arranged in a layered-like motif, perpendicular to [110] with an interlayer distance of 9.3 Å (Fig. 6c), which is associated with the characteristic 110 basal reflection (Fig. 2c). Although the crystal structure of the 1-3-2 phase with its layered motif (Fig. 6b) completely differs, the strong 002 basal reflection is located at an identical position (Fig. 2b) which is attributed to an identical interlayer distance of 9.3 Å (Fig. 6d). This can lead to serious problems for the phase identification using XRPD

Fig. 7 Illustration of the interaction of the chains in the crystal structure of the 2-1-5 phase, mediated by non-coordinated water molecules.

only. Usually this process is carried out with flat plate devices, *i.e.* samples may exhibit preferred orientation. In addition, the second most intense reflection of the 2-1-5 phase (200) exhibits a relative intensity of 12.4% and the relating reflection of the 1-3-2 phase (004) has a relative intensity of 18.2%. Therefore, phases are often assigned to the appearance of the characteristic strongest reflection. This can be misleading when dealing with mixtures containing the 2-1-5 phase or the 1-3-2 phase, which is a possible explanation for contradictory data given in the literature. Accordingly, complementary methods like vibrational spectroscopy are essential for unambiguous phase identification.

Spectral properties

The 2-1-5 phase exhibits a characteristic light blue colour (Fig. 8a) that can be clearly distinguished from the turquoise 1-3-2 phase (b) and the deep blue 1-2-0 phase (c). This is reflected by the diffuse UV/VIS reflectance spectra, as well

Fig. 6 Comparison of main motifs of the crystal structures of the 2-1-5 (a, c) and the 1-3-2 phase (b, d).

Fig. 8 Photographs of powder samples of the (a) 2-1-5 phase, (b) 1-3-2 phase and (c) 1-2-0 phase and comparison of normalised the UV/VIS reflectance spectra (d).

(Fig. 8d). The 1-2-0 phase shows a sharp reflectance maximum at 472 nm, the maximum of the 2-1-5 phase is slightly broader and located at 488 nm and the reflectance maximum of the

1-3-2 phase at 517 nm is very broad and shifted further towards higher wavelengths, *i.e.* towards greenish. Historic verdigris pigments, which are often the multiphase mixture, usually exhibit a broad reflection maximum at approx. 500 nm,³⁸ this can be explained by a superposition of the UV/VIS spectra presented in Fig. 8d.

The FT-IR and Raman spectra of the 2-1-5 phase are given in Fig. 9. For the band assignment, the spectroscopic data of the 1-3-2 phase,^{7,8,10,13} the 1-2-0¹⁵ phase, $\text{Cu}(\text{CH}_3\text{COO})_2 \cdot \text{H}_2\text{O}$ ^{39,40} and $\text{Cu}(\text{OH})_2$ ⁴¹ as well as the fundamental vibrations of the acetate ion⁴² were used. By band assignment and interpretation of the FT-IR-spectrum, several features of the crystal structure can be confirmed. The Raman spectrum was recorded to obtain reference data for substance identification.

In the high wavenumber region of the FT-IR-spectrum (Fig. 9a, top), a superposition of very broad and intense bands (1) with a maximum at 3127 cm^{-1} is visible, which can be assigned to water related OH-stretching modes. Due to the low sensitivity of ATR units in the high wavenumber region and the high intensity of water related OH-stretching modes, hydroxide related OH-stretching modes that usually materialise as sharp bands cannot be identified. The acetate related C-H stretching modes (2) are rather broad, which indicates that the orientation of the methyl groups is not fixed by strong C-H...O bonds. The mid wavenumber region (Fig. 9b, top) contains symmetric and asymmetric acetate related C-O stretching modes ((3), (4)), as well as C-H bending modes (5). From the

Fig. 9 FT-IR spectrum of the 2-1-5 phase and comparison of the Raman spectra of the verdigris phases 2-1-5 (black), 1-3-2 (turquoise) and 1-2-0 (blue) in the high (a), mid (b) and low (c) wavenumber region.

C–O stretching modes, valuable information on the crystal structure can be drawn. Both the symmetric and the asymmetric C–O stretching modes are split into several bands which are attributed to the different coordination spheres of the 4 distinct acetate sides in the crystal structure of the 2-1-5 phase (Fig. 5b). The splitting of the strongest symmetric (1402 cm^{-1}) and the strongest asymmetric C–O stretching mode (1526 cm^{-1}) in the IR-spectrum is unusually small, $\Delta\nu = 124\text{ cm}^{-1}$ (Fig. 9b, top, Table 1). For ionic acetate, usually a splitting of $\approx 160\text{ cm}^{-1}$ can be expected.⁴³ A smaller splitting indicates bidentate or bridging coordination. Therefore, these bands are most likely assigned to the pseudo bidentate and pseudo bridging acetates (b) and (c) (Fig. 5b). A small band related to a symmetric C–O stretching mode is apparent at 1445 cm^{-1} . The splitting between this band and the strongest asymmetric C–O stretching mode (1526 cm^{-1}) is extremely small ($\Delta\nu = 81\text{ cm}^{-1}$), and therefore it can be assigned to the acetate (a) which has a *bidentate* and *bridging* characteristic. The splitting ($\Delta\nu = 167\text{ cm}^{-1}$) between the broad asymmetric C–O stretching mode at 1569 cm^{-1} and the strongest symmetric C–O stretching mode (1402 cm^{-1}) is slightly greater than that expected for ionic acetates. Hence, it can be assigned to *monodentate* coordinating acetate (d). In the low IR-region (Fig. 9c, top), various acetate related C–C-stretching modes (7), carboxylate related bending modes (9), and Cu–O related bands (10) are apparent. In addition, broad hydrate water related OH-bending modes are present.

A comparison of a part of the Raman spectra of the known verdigris phases is presented in Fig. 9, bottom. Due to the presence of strong hydroxide related OH-stretching modes, the 1-2-0 phase (blue) line can be clearly distinguished from other

verdigris phases. The Raman-spectra of the 2-1-5 (black line) and the 1-3-2 phase (turquoise line), however, are very similar, and hence distinguishing between these two phases is not trivial. Small differences are visible in the mid (4) and low wavenumber (9 and 10) regions. Using conventional Raman-devices, these bands, however, are very broad and have only a little intensity. The sharp methyl related CH-stretching (2) and the bending mode (7) are more favourable for phase identification. In the 1-3-2 phase, these modes are slightly shifted towards lower wavenumbers than in the 2-1-5 phase (Fig. 9, bottom, inserts).

The complete Raman and FT-IR spectra of the 2-1-5 phase are presented in the ESI, Fig. S4.†

Thermal behaviour

The complex thermal behaviour of the 2-1-5 phase was investigated by thermogravimetric (TG) analysis, as well, as by *ex situ* and *in situ* XRPD.

The TG-curve (Fig. 10, black line) of the 2-1-5 phase exhibits several overlapping steps and the step size can only be estimated by using the DTG-curve (green line), *i.e.* the first derivative of the TG-curve. The thermal decomposition of the 2-1-5 phase starts at $50\text{ }^\circ\text{C}$. The first decomposition step is associated with a mass loss of $\approx 6.2\text{ wt}\%$, which corresponds to a release of 2 molecules of hydrate water (calculated mass loss: $6.5\text{ wt}\%$). In the *in situ* XRPD patterns (Fig. 11a and b), the intensity of the reflections of the 2-1-5 phase starts to decrease at $50\text{ }^\circ\text{C}$ and additional reflections appear. This process is completed at $70\text{--}90\text{ }^\circ\text{C}$. According to the measured mass loss, the additional reflections can be assigned to a phase having a 2-1-3 composition. The XRPD pattern of this phase (Fig. 12b) exhibits a very strong basal reflection corresponding to a lattice plane distance of 8.6 \AA that points to a layered-like structure motif of this phase. In the TG-curve (Fig. 10, black

Fig. 12 *In situ* XRPD patterns of the 2-1-5 phase taken during the thermal decomposition at (a) 30 °C, (b) 90 °C, (c) 150 °C + *in situ* XRPD patterns taken during the decomposition of the 1-2-0 phase at 170 °C (blue) and of the 1-3-2 phase taken at 140 °C (turquoise), (d) 210 °C + *in situ* XRPD patterns taken during the decomposition of $\text{Cu}(\text{CH}_3\text{COO})_2 \cdot \text{H}_2\text{O}$ at 200 °C (grey) and (e) at 270 °C + *in situ* XRPD patterns taken during the decomposition of $\text{Cu}(\text{CH}_3\text{COO})_2 \cdot \text{H}_2\text{O}$ at 270 °C (grey).

line), there is no pronounced plateau between the first and the second decomposition step, accordingly the DTG-curve (green line) does not drop down to 0 (grey line). The mass loss starts quickly in the second decomposition step but decelerates in course of the decomposition process. Finally, there is an

overlap with the subsequent third decomposition step. With respect to the minimum in the DTG-curve, the second decomposition step is completed at a total mass loss of ≈ 15.8 wt%, which corresponds to the complete release of hydrate water (calculated mass loss 16.4 wt%). According to the *in situ* XRPD analysis (Fig. 11b and c), the decomposition of the intermediately formed 2-1-3 phase starts at 110 °C and yields two solid phases: anhydrous copper(II)-acetate (Fig. 12c, reflections indicated by ∇) and a solid with a characteristic basal reflection associated with a lattice plane distance of approx. 10.5 Å. The latter phase also occurs during the thermal decomposition of the 1-3-2 (Fig. 12c, turquoise pattern) and the 1-2-0 phases (blue pattern). In the case of the 1-2-0 phase, the intermediate was identified as $\text{Cu}_3(\text{CH}_3\text{COO})_2(\text{OH})_{4-2x}\text{O}_x$ ¹⁵ and in the case of the 1-3-2 phase as $\text{Cu}_2(\text{CH}_3\text{COO})(\text{OH})_3$ (\equiv 1-3-0 phase).⁷ Hence, the intermediate formed during the thermal decomposition of the 2-1-5 phase is most likely an acetate-hydroxide ($\text{Cu}(\text{CH}_3\text{COO})_x(\text{OH})_{1-x}$) with a variable acetate : hydroxide ratio. At 190 °C, the intensity of the $\text{Cu}(\text{CH}_3\text{COO})_x(\text{OH})_{1-x}$ related reflections starts to decrease, the reflections attributed to anhydrous copper(II)-acetate increase in intensity and additional reflections attributed to Cu_2O appear (Fig. 11c, d and 12d). The course of the TG- (Fig. 10, black line) and DTG-curve (green line) indicates that this process runs slowly. At 250 °C, the final decomposition step starts. The DTG-curve reveals that this is a two-step process (Fig. 10, (4) and (5)), which is also confirmed by the *in situ* XRPD analysis (Fig. 11d and e). Anhydrous copper(II)-acetate is decomposed to a strongly stacking faulted oxy-acetate, $\text{Cu}(\text{CH}_3\text{COO})_{1-2y}\text{O}_y$, that is characterised by a strong basal reflection corresponding to a lattice plane distance of 10.0 Å (Fig. 12e). As the complete decomposition of the acetate ion under a nitrogen atmosphere leads to several redox processes, copper(II) is reduced to copper(I) and copper(0). An *ex situ* XRPD analysis of the brownish-red residue of the thermal decomposition shows that it consists of Cu_2O and Cu (ESI, Fig. S5†); this is in accordance with the literature data of the thermal decomposition of copper(II)-acetate.^{40,44}

Magnetic properties

Fig. 13 displays the inverse magnetic susceptibilities of a 2-1-5 polycrystalline sample *versus* the temperature measured by applying an external magnetic field of 0.1, 1 and 7 Tesla. One observes a field dependence leading to slight growth of the inverse susceptibilities with higher magnetic fields. This effect can be understood as due to a minute ferromagnetic impurity which becomes gradually more saturated with larger external fields. Saturation effects are also observed at a very low temperature where especially the 7 T data exhibit a levelling-off at a finite value whereas the 0.1 and 1 T inverse susceptibilities to a good approximation exhibit a linear temperature dependence for $T \rightarrow 0$ indicating Curie-Weiss behaviour, $\chi = C/(T - \theta)$, with a vanishing Curie-Weiss temperature, θ , whereas above ~ 100 K, the susceptibilities follow the Curie-Weiss law at a Curie-Weiss temperature of $-64(2)$ K considering the 7 T data. What is also immediately obvious is the marked change of the slopes

Fig. 13 Magnetic susceptibilities of a powder sample of the 2-1-5 phase (per three Cu atoms) measured by heating the sample from 2 K to 300 K in an external field of 0.1, 1 and 7 Tesla as indicated.

Fig. 14 Fit of eqn (1) to the magnetic susceptibility of a powder sample of the 2-1-5 phase (per three Cu atoms) measured in an external field of 7 Tesla.

($1/\chi \propto 1/C$) of the Curie–Weiss laws at high and at low temperatures by a factor of ~ 2.7 . Since the Curie–Weiss constant C is proportional to the number of active magnetic species, the slope change indicates a marked reduction of the contributing Cu moments by a ratio of approximately three. The Curie–Weiss temperature reflects the predominant spin exchange coupling between magnetic moments. Apparently, the magnetic species left at low temperatures remain almost uncoupled whereas at high temperatures, significant spin exchange coupling prevails. In view of the crystal structure of the 2-1-5 phase, this finding is suggestive of a scenario where a rather strongly antiferromagnetically spin exchange the coupled magnetic Cu–Cu dimer and a significantly weaker coupled Cu monomer contribute to the magnetism. The Curie contribution of the latter diverges (*i.e.* $\theta \rightarrow 0$) at low temperatures whereas the former condense into non-magnetic singlets with vanishing magnetic response at temperatures below the singlet–triplet splitting energy of the spin $S = 1/2$ Cu²⁺ dimers. At temperatures sufficiently high compared to the spin exchange coupling energy of the spin dimers, both subsystems contribute to the magnetisation. Accordingly, we have fitted the magnetic susceptibility of the 2-1-5 phases to the sum of the susceptibility of a $S = 1/2$ dimer given by the Bleaney–Bowers equation⁴⁵ and a Curie-law contribution from the monomer according to

$$\chi_{\text{mol}}(T) = 2 \frac{N_A \mu_B^2 g_{\text{dim}}^2}{3k_B T} \left[1 + \frac{1}{3} e^{(-J_{\text{dim}}/k_B T)} \right]^{-1} + \frac{N_A \mu_B^2 g_{\text{mono}}^2}{3k_B T} + \chi_0, \quad (1)$$

where we have added a temperature independent part, χ_0 , which takes care of diamagnetic contributions from the electrons in the closed shells and from the temperature-independent paramagnetic Van Vleck susceptibility contributions. The diamagnetic contributions can be estimated from Pascal's increments⁴⁶ for the contributing ions. The van Vleck contributions are orientation dependent and are of the order of $+100 \times 10^{-6} \text{ cm}^3$ per mol per Cu²⁺ cation and can compensate or even override the diamagnetic contributions.⁴⁷

Fig. 14 displays a fit of the susceptibility data (7 T) to eqn (1) with parameters summarised in Table 2.

Table 2 Parameters resulting from a fit of eqn (1) to the magnetic susceptibility data collected as a function of temperature between 2 and 300 K in an external magnetic field of 7 Tesla

g_{dim}	2.19(1)
g_{mono}	2.390(5)
J_{dim}	−182(1) K
χ_0	$297(12) \times 10^{-6} \text{ cm}^3 \text{ mol}^{-1}$

The agreement of the fit with the experimental data is very satisfactory thus giving strong support for our model assumptions that the magnetic properties of the 2-1-5 phase decompose into two independent subsystems. The fit parameters (Table 2) indicate an antiferromagnetic spin exchange coupling of −182 K in the Cu dimer. This value is about 50% of that what is typically found *e.g.* in hydrated copper acetate [Cu(OAc)₂·H₂O]₂ where values of ~ -400 K or somewhat more have been observed.⁴⁸

The g factor for the dimer is close to what is expected for a powder average of the Cu²⁺ g factors, ~ 2.13 – 2.15 .⁴⁹ The g factor of the monomer is somewhat enlarged. A reason could be that an impurity phase containing Cu²⁺ $S = \frac{1}{2}$ entities contribute in the same way to the susceptibility as the Cu monomer of the 2-1-5 phase.

Conclusions

Copper(II)-acetate hydroxides ($x\text{Cu}(\text{CH}_3\text{COO})_2 \cdot y\text{Cu}(\text{OH})_2 \cdot z\text{H}_2\text{O} \equiv x - y - z$ phase) are known as the main components of historic verdigris pigments. Incomplete precipitation from aqueous copper(II)-acetate solution at elevated temperatures using ammonia solution as a precipitating agent leads to the formation of the well characterised 1-3-2 and 1-2-0 phases. By further ageing of the mother liquors at 25 °C for one year, additional verdigris phases can be obtained. From the mother liquor from the production of the 1-3-2 phase, the hitherto poorly characterised 2-1-5 phase was crystallised. The phase composition was confirmed by crystal structure determination from laboratory XRPD data and thermal analysis. In the crystal

structure of the 2-1-5 phase, copper ions are coordinated by acetate and hydroxide ions, as well as by water molecules forming distorted square planar coordination spheres. The acetate ions act as bidentate and bridging, monodentate and apical and as pseudo bidentate and pseudo bridging (*i.e.* there is still some interaction between the non-coordinating carboxylate oxygen and a copper ion) ligands. This is also reflected by splitting and degeneration of the symmetric and asymmetric carboxylate related C–O stretching modes in the IR-spectrum. $\text{Cu}_2(\text{CH}_3\text{COO})_2(\text{CH}_3\text{COO})_{1/2}(\text{OH})_{4/3}\text{H}_2\text{O}^{1/6+}$ dimers that are interconnected by $\text{Cu}(\text{CH}_3\text{COO})(\text{CH}_3\text{COO})_{1/2}(\text{OH})_{2/3}^{1/6-}$ squares forming chains running in the *c*-direction are the main motif of the crystal structure of the 2-1-5 phase. This motif is reflected by the magnetic properties that show a rather strongly antiferromagnetically spin exchange coupled magnetic Cu–Cu dimer and a significantly weaker coupled Cu monomer contributing to the magnetism. In the crystal structure, additional molecules of hydrate water are situated inbetween the sheets and mediate the inter-chain interaction. These loosely bound water molecules can be easily released by heating up to temperatures >50 °C. The light blue colour of the solid originates from a reflectance maximum at 488 nm and significantly differs from known verdigris phases. An investigation of several historic verdigris pigment samples reveals that the 2-1-5 phase occurs both as minor and major components. Hence, reliable reference data for the identification of the 2-1-5 phase by XRPD or vibrational spectroscopy are now available that can be used by museums and collections worldwide to identify this verdigris phase in historic artwork and pigment samples.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

David A. Scott's¹ enthusiasm for historic pigments and their synthesis greatly inspired our work. Julia Kröger from the Max Planck Institute for Solid State Research is acknowledged for measuring the UV/VIS spectrum, Eva Brücher from the Max Planck Institute for Solid State Research for performing the SQUID measurements, Jörg Stelzner from the State Academy of Art and Design Stuttgart for taking the Raman-spectrum and Michael X. Müller from the University of Stuttgart is acknowledged for taking the IR spectrum. Funding by DFG for the project "In search of structure" (grant EG 137/9-1) is gratefully acknowledged. Open Access funding provided by the Max Planck Society.
