Inter-individual, inter-city, and temporal trends of per- and polyfluoroalkyl substances in human milk from Swedish mothers between 1972 and 2016†

Elisabeth Nyberg, a,b Raed Awad, b Anders Bignert, a Caroline Ek, a Gerd Sallsten a and Jonathan P. Benskin a,b

Inter-individual, inter-city, and temporal trends of 19 per- and polyfluoroalkyl substances (PFASs) were investigated in human milk collected in Stockholm (1972–2016) and Gothenburg (2007–2015), Sweden. The concentrations of perfluorohexane sulfonate (PFHxS), perfluorononanoate (PFNA), perfluorodecanoate (PFDA), perfluoroundecanoate (PFUnDA), and perfluorotridecanoate (PFTrDA) in human milk from Stockholm increased significantly over the entire monitoring periods, whereas branched (Br) and linear (L) isomers of perfluorooctane sulfonamide (FOSA) decreased. In human milk from Gothenburg, significant downward trends were detected for perfluorodecanoate (PFDoDA), PFHxS and Br-perfluorooctane sulfonate (Br-PFOS) over the last decade. This declining trend was also observed for perfluorohexanoate (PFHxA), PFHxS, perfluoroctanoate (PFOA) and Br-PFOS in Stockholm over the same time period. No significant differences were observed in concentrations or relative PFAS profiles between Stockholm and Gothenburg. However, a comparison of the PFAS profile in Stockholm milk revealed distinct profiles for the time periods 1972–1996, 2000–2012, and 2013–2016, reflecting a shift in exposure over time. The lower bound estimated daily intake (EDI) for \( \sum \)PFAS concentrations in infants ranged from 7.1–40 ng per kg body weight per day (ng/kg bw/d) in Stockholm and from 5.2–25 ng/kg bw/d in Gothenburg over the studied time period, consistent with other European countries. Overall these data indicate that exposure to some legacy PFASs via breastmilk is declining, presumably as a result of regulation and phase-out initiatives. However, increasing concentrations for other PFASs and a shift in the overall PFAS profile in recent years may pose an ongoing health risk to infants.

Environmental significance
Per- and polyfluoroalkyl substances (PFASs) are anthropogenic substances which contaminate human blood globally. In breastfed infants, human milk is among the most important sources of PFAS exposure. Characterizing PFAS levels and time trends in breast milk is therefore important for assessing risks to infants. In the present work, we analyzed 19 PFASs (plus branched isomers) in human breastmilk from Stockholm (1972–2016) and Gothenburg (2007–2015), Sweden. These substances stems mostly from the occurrence of perfluoroalkyl acids (PFAs; a sub-class of PFAS) in the global environment, including water, soils, sediment, wildlife and

Introduction
Per- and polyfluoroalkyl substances (PFASs) are a class of over 3000 anthropogenic substances that have been manufactured for over six decades. Owing to their stability and amphipathic properties, PFASs have been used in a wide range of commercial processes and consumer products. Concern over the use of these substances stems mostly from the occurrence of perfluoroalkyl acids (PFAs; a sub-class of PFAS) in the global environment, including water, soils, sediment, wildlife and
humans. PFAAs have been linked to a wide range of adverse health effects, including neuro- and immune toxicity, endocrine disruption, and cancer (see review by DeWitt). Long chain PFAAs are extremely biopersistent, with human blood elimination half-lives on the order of several years.

Acknowledgement of the risks associated with long chain PFAAs has led to a number of regulatory and industry phase-out initiatives over the past 17 years. In the year 2000 one of the major global PFAA manufacturers, 3M, began phasing out production of perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) and their hydrolysis products, including perfluorooctanoic acid (PFOA). North American PFAA manufacturers subsequently volunteered to phase out long-chain PFAAs by 2015, and in 2007, PFOS and PFOA were added to Annex B of the International Stockholm Convention on Persistent Organic Pollutants. Nevertheless, production of PFOS-related products continues in some countries under production and use exemptions and recent studies have reported environmental contamination from the increasing use of alternative fluorinated substances.

Routes of human exposure to PFASs for the general population include food, house dust, air, and drinking water. In infants, occurrence of PFASs is attributed to placental transfer while in the womb, and breastfeeding post-partum. It is estimated that 94% of PFOS intake and 83% of PFOA intake in 6 month-olds is attributable to lactational exposure. Model simulations and empirical data have demonstrated that daily intake through breastfeeding and the resulting internal PFAS levels can be higher in nursing infants than in mothers. Several studies have also shown that maternal PFAS levels decrease during breastfeeding and that PFAS levels in children are correlated to breastfeeding duration, with as much as 2-fold higher mean PFAS concentrations for breastfed infants compared to non-breastfed. Clearly, the effect of PFAS exposure on the health of both mother and baby is of concern. Several studies have reported links between PFAS exposure and perturbation in lipid metabolism and glucose tolerance during pregnancy. Exposure to some PFASs during early life stages has also been linked to adverse health effects such as reduced birth weight and immune toxicity.

Previously, Sundström et al. reported statistically significant declines in PFOS and PFOA concentrations from 2001–2008 in pooled human milk from Stockholm, Sweden. These trends paralleled time trends observed in human serum from other parts of the world. However, Sundström et al. only measured 3 substances – PFOS, PFOA, and PFHxS; numerous other PFASs may exist in breast milk, thereby posing additional risk to infants. Time trends for some PFASs continue to increase in human serum in some parts of the world, including Sweden. Thus, the main objective of the present work was to improve characterization of PFAS contamination in Swedish breastmilk by generating time trends from 1972 to 2016 for an additional 16 PFASs (i.e. a total of 19 PFASs + branched isomers). The second objective was to compare PFAS time trends and inter-individual differences in milk from Stockholm to another city, Gothenburg, in order to assess possible differences in exposure between cities (e.g. due to geographical and/or socioeconomic variation). Finally, PFAS concentrations were used to determine estimated daily intakes (EDIs) for infants which were compared to threshold levels designed to be ‘safe’ for infant exposure.

### Experimental

#### Sampling

Human milk samples from Stockholm and Gothenburg were mainly collected through the Mothers’ Milk Centre at Stockholm South General Hospital and the Institution for Work and Environmental Medicine at Gothenburg University, respectively. Samples were collected between 2 weeks to 3 months after delivery from healthy native Swedish mothers, who were predominately non-smokers and primiparous (Table 1). There were a total of 20 pooled samples analyzed from Stockholm (1972–2016), containing 9–116 individual samples per pool, and 11 pooled samples from Gothenburg (2007–2015), containing 5–11 individuals per pool. Due to the limited availability of stored samples, the number of subjects in each pool varied considerably. In addition, samples collected in 2012 (16 from Gothenburg and 20 from Stockholm) and in 2016 (10 from Stockholm) were analyzed individually (Table 1). Samples were initially stored at −18 °C in plastic bags and bottles. Upon being shipped to the Environmental Specimen Bank at the Swedish Museum of Natural History in Stockholm, samples were thawed, transferred to pre-washed glass bottles with lids and stored at −20 °C.

#### Materials and Methods

Results of the present study were generated from 147 individual samples, including 116 stored samples and 31 available from thawed samples.

Standards and reagents

Linear isomer standards of perfluoropentanoate (PFPeA), perfluorohexanoate (PFHxA), perfluoroheptanoate (PFHpA), PFOA, perfluorooctanoate (PFOA), perfluorodecanoate (PFDoDA), perfluorododecanoate (PFDoDA), perfluorotridecanoate (PFTrDA), perfluorotetradecanoate (PFTrDA), 3-perfluoroheptyl propanoic acid (FHpPA), perfluorobutane sulfonate (PFBS), perfluorohexane sulfonate (PFHxS), PFOS, perfluorodecane sulfonate (PFDS), perfluorooctanesulfonamide (FOSA), N-methyl perfluoroctane sulfonamidoacidic acid (MeFOSAA), and N-ethyl perfluorooctane sulfonamidoacidic acid (EtFOSAA) were obtained from Wellington Labs (Guelph, ON, Canada). All isotopically labeled standards were obtained from Wellington Labs (a full list is provided in Table S1, ESI†). Formic acid, ammonium sulfate, and ammonium acetate were obtained from Merck. Potassium hydroxide was purchased from VWR, methyl tert-butyl ether (HPLC grade) was purchased from RATHBURN (Walkerburn, Scotland) and acetonitrile was obtained from Honeywell. Standard Reference Material (SRM) 1954: Organic Contaminants in Fortified Human Milk, was obtained from the National Institute of Standards and Technology (NIST).

Chemical analysis

Breast milk aliquots (2 mL each) were extracted according to a previously published method.28 Briefly, after acidifying with formic acid, each sample was spiked with isotopically labeled internal standards. Samples were then vortexed, fortified with 600 μL of saturated ammonium sulfate, and then vortexed again. Following addition of acetonitrile (7 mL), samples were placed on a mechanical shaker for 30 minutes, after which they were centrifuged. The top organic layer was transferred into a polypropylene tube and evaporated at 40 °C. The extract was then diluted with 300 μL of pure water and vortexed before adding 500 μL of 1 M potassium hydroxide. The tube was vortexed and then supplemented with 7 mL of methyl tert-butyl ether, then placed in a mechanical shaker for 20 minutes followed by centrifugation. The organic layer was subsequently transferred into a clean polypropylene tube. The extracts were evaporated at 40 °C and then fortified with 200 μL of buffer (1:2:1 ammonium acetate: acetonitrile: water). After vortexing and centrifugation, the lower layer was transferred to microvial for instrumental analysis.

Instrumental analysis (Table S1, ESI†) was carried out using an ultra performance liquid chromatograph (UPLC) coupled to a Xevo TQ-S triple quadrupole mass spectrometer (Waters) operated in negative ion electrospray ionization, selected reaction monitoring mode. Extracts were chromatographed on a BEH C18 analytical column (2.1 × 50 mm, 1.7 μm particle size, waters) operated at a flow rate of 0.4 mL min⁻¹, using a mobile phase composition of 90% water/10% acetonitrile containing 2 mM ammonium acetate (solvent A) and 100% acetonitrile containing 2 mM ammonium acetate (solvent B). The gradient profile is provided in Table S2, ESI†. A total of two precursor/product ion transitions were monitored per analyte; one for quantification and the other for qualification (Table S1, ESI†).

Quantitative determination of target compounds was carried out by isotope dilution or an internal standard approach using a linear calibration curve with 1/x weighting. Branched isomers were determined semi-quantitatively using the calibration curve for the linear isomer. The concentration of perfluoropentanoate (PFPeDA) was also estimated semi-quantitatively using the calibration curve for PFPeDA. With the exception of PFOA and PFOS, primary ions were always used for quantification. For PFOA, the m/z 413/169 ion was used for quantification because of an interference in m/z 413/369. For PFOS, concentrations are reported as the average of m/z 499/80 and 499/99 ions for both branched and linear isomers, as described in Riddell et al.35 Sum PFOS was then obtained by summing the concentrations of branched and linear PFOS.

Quality control

Laboratory background contamination was monitored by including procedural blanks (2 mL Milli-Q water, n = 4) during the processing of real samples. Method accuracy and precision were assessed using replicate quality control samples, consisting of SRM 1954 (n = 3) and bovine milk analyzed with a low-(0.48–2.03 ng mL⁻¹, n = 4), or high- (1.44–6.10 ng mL⁻¹; n = 4) spike of PFAs (Table S3, ESI†). Finally, concentrations of PFOS, PFOA, and PFHxS from 1972–2008 reported in Sundström et al.39 were compared to data generated in the present work (Fig. S1, ESI†).

Data handling

For lower bounds (LB) estimates of sum (∑₁₉) PFAS concentrations, values <LOQ were replaced with ‘0’. For upper bounds (UB) estimates, concentrations <LOQ were replaced with ‘0’ in cases where a substance was not detected in any sample; in all other cases values <LOQ were replaced with LOQ/2"¹. Temporal trend analysis was performed by log-linear regression for the entire monitoring period and for the most recent ten years using the yearly arithmetic mean values. In cases where a nonlinear trend was more representative of the development over time, a 3-point running mean smoother was checked for statistical significance compared to the regression line using ANOVA.36 In addition, non-linear trends were investigated using change-point detection, a method that iteratively searches for two log-linear lines with different slopes that explain significantly more of the total variance than a single regression line fitted for the whole monitoring period.37 Potential outliers were detected using a method described by Hoaglin and Welsch.38 However, potential outliers are still included in the statistical calculations. The statistical treatment used for trend detection is explained in more detail in Nyberg (2016).39 PFASs for which data for more than 70% of the years were below LOQ (i.e. PFPeA, PFPeDA, FHPPA, PFDS, MeFOSAA and EtFOSAA) were excluded from the trend analysis. Principal Component Analysis (PCA) was applied to PFAS profiles (i.e. concentration data converted to a percentage of the ∑PFAS concentration) to study difference
in PFAS patterns between Stockholm and Gothenburg (for samples collected 2007–2016) and also over time (1972–2016) in Stockholm. This method is described in more detail in Glynn et al.44 Hotelling’s $T^2$ tests were performed to check for significant differences in PFAS patterns between the periods 1972–1996, 2000–2012 and 2013–2016. The test was repeated and thus the significance level of $\alpha = 0.05$ was Bonferroni adjusted. An $F$-test was used to test if the variances differed significantly between the samples with individual measurements from Stockholm and Gothenburg in 2012. Only PFASs with $>50\%$ of data above LOQ were included in both the $F$-test and the PCA on differences in PFAS pattern between Stockholm and Gothenburg. For the PCA examining differences in PFAS patterns in Stockholm over time, $>70\%$ of data above LOQ was set as the threshold for inclusion in the analysis. To analyze the impact of confounding factors (e.g. age and parity) on measured concentrations multiple regressions were used. Values below LOQ were divided by the square root of 2 prior to inclusion in the statistical calculations.

Results and discussion

Quality control

Blank concentrations were typically below method detection limits for most targets (Tables S5–S7, ESIT). The exceptions were for PFBA, PFNA, and FOSA, where low concentrations (<12 pg mL$^{-1}$) were consistently observed, which was attributed to the Milli-Q water used to prepare them (and which was not added to real samples). Consequently, blank concentrations were not subtracted from concentrations in real samples. One blank also contained high concentrations of PFHxS, PFOA, PFPeA, PFHxA, PFOA, and PFNA (again arising from the Milli-Q water used to prepare it), but this was deemed anomalous since concentrations in real samples from the same batch, as well as blanks, samples, and QCs from subsequent batches, were all well below these levels.

For most substances, method accuracy and precision were good at both fortifications levels, with mean (± standard error of the mean (SEM)) percent recoveries ranging from 73 ± 1.7% to 129 ± 3.5% and 73 ± 3.9% to 132 ± 4.4% at low- and high-spiking levels, respectively. PFHpA, PFBS, and FHpPA displayed lower recoveries at both fortification levels (9–63%), likely due to an absence of exactly-matched, isotopically-labelled internal standards. Nevertheless, precision remained excellent for these substances and they were detectable at the low fortification level. PFHpA, PFBS, and FHpPA were therefore included in further data processing, albeit with the caveat that concentrations reported here may be underestimated for these targets.

External validation of the method was achieved through (a) comparison of PFAS concentrations measured in SRM 1954 ($n = 3$) to those reported by Keller et al.41 (Table S4, ESIT) and (b) through comparison of PFHxS, PFOA, and PFOA concentrations from 1972–2008 (Stockholm) generated here to concentrations reported previously for these targets in Sundström et al.28 (Fig. S1, ESIT). In general, concentrations reported in the present work were similar or at the lower end of the range reported by Keller et al.41 (2010). The exceptions were for PFHxS, which was higher and displayed wider variability than concentrations reported in Keller et al.,41 and PFOA, which was considerably lower in the present work. Given the very low concentrations (i.e. typically ~tens of pg mL$^{-1}$) in milk, overall method accuracy and precision was good. Notably, we have reported PFPeA, PFTeDA, PFPeDA, PFHpPA, PFDS, MeFOSAA, and EtFOSAA concentrations in SRM 1954 for the first time (Table S4, ESIT). Finally, a comparison of PFHxS, PFOA, and PFOA concentrations observed here against those in Sundström et al. revealed good correlations ($r^2 = 0.72–0.80$) with concentrations of PFOA and PFOA distributing approximately evenly above and below the line of $y = x$ (Fig. S1†). PFHxS concentrations were mostly situated above this line, indicating slightly lower concentrations in the present work versus Sundström et al. (Fig. S1†). Percent differences (i.e. |Sundström-present study|/Sundström) of 18, 19, and 31% for PFOA, PFOA, and PFHxS, respectively, confirmed that the differences were minor between studies. Overall these data demonstrate good method performance and study intercomparability.

PFAS profiles

$\sum_{19}$PFAS concentrations in pooled samples from Stockholm (1972–2016) ranged from 110–470 pg mL$^{-1}$ for LB estimates (Fig. 1) and from 130–490 pg mL$^{-1}$ for UB estimates. In Gothenburg (2007–2015) $\sum_{19}$PFAS concentrations ranged from 110–220 pg mL$^{-1}$ (LB) and from 130–230 pg mL$^{-1}$ (UB). A PCA of PFAS profiles in Stockholm and Gothenburg from 2007–2015 revealed no significant difference in patterns (Fig. 2B), implying the predominant source of PFAS exposure in mothers from both cities is similar.

The highest $\sum_{19}$PFAS concentration observed among all samples was for the year 1988 from Stockholm (Fig. 1). Across all years and in both cities, PFOA (sum isomers) and PFOA were consistently the dominant PFASs. The only exception was for PFHxS, which was intermittently detected at concentrations of up to 80 pg mL$^{-1}$ in 1984 and at concentrations up to 130 pg mL$^{-1}$ in an individual from 2016. Concentrations of PFOS reported here were within or below the range of average concentrations (46–260 pg mL$^{-1}$; arithmetic means) reported in a worldwide review42 for 2006–2010. Another review,43 which included studies from 2008–2015, reported somewhat lower levels (arithmetic means) of PFOS in human milk, more in accordance with concentrations in the present study. PFOA concentrations in this study was also in line with concentrations reported previously (about 40–150 pg mL$^{-1}$).41

PFAS concentrations in individuals sampled in 2012 from Stockholm and Gothenburg are provided in Fig. 3. $\sum_{19}$PFAS concentrations ranged from 83–290 pg mL$^{-1}$ (LB) and 110–310 pg mL$^{-1}$ (UB) for Stockholm ($n = 20$) and 61–290 pg mL$^{-1}$ (LB) and 90–320 pg mL$^{-1}$ (UB) for Gothenburg ($n = 16$). As was the case in pooled samples, the profiles in individuals were dominated by PFOS (sum isomers) and PFOA at concentrations of 53 ± 27 and 53 ± 24 pg mL$^{-1}$ (arithmetic mean of individuals from both cities ± standard deviation), respectively. Notably, FHpPA was observed in 8 samples from Stockholm at concentrations
up to 42 pg mL\(^{-1}\) and 1 sample from Gothenburg at a concentration of 15 pg mL\(^{-1}\). This target was not observed in blanks. To our knowledge FHpPA has not previously been reported in human milk. This substance (also known as 7 : 3 fluorotelomer acid), is a stable transformation production of 8 : 2 fluorotelomer alcohol (FTOH), which is incorporated into a wide range of consumer products. FHpPA was previously reported at concentrations up to 3.9 ng mL\(^{-1}\) in serum from ski wax technicians.\(^4\) The short-chain PFOS replacement PFBS also appeared in individuals from Gothenburg at a higher frequency (7/16 samples) compared to Stockholm (1/20 samples). Among PFASs detectable in over 50% of samples, coefficients of variation (CVs) for individual PFASs were not statistically different, with the exception of FOSA (\(F\)-test; \(p = 0.0087\)), which displayed greater variability in Gothenburg. In both cities, the highest CVs were observed for PFTeDA, while the lowest CVs were observed for PFOA, PFUnDA and PFNA.

**Temporal trends**

The concentrations of PFHxS, PFNA, PFDA, PFUnDA, and PFTrDA increased significantly (3.3–3.7% per year) between 1972 and 2016 in Stockholm (Table 2, Fig. 4) whereas a significant downward trend was observed for Br- and L-FOSA (−3.2 and −4.8% per year respectively, Table 2, Fig. 4 and S3, ESI†).
Concentrations of PFHxS, Br-PFOS and PFDODA, decreased significantly between 2007 and 2015 in the milk samples from Gothenburg (Fig. S2 and S3, ESI†). Significant upward–downward change-point trends (Table 3) were detected in Stockholm for Br- and L-PFOS (1988), PFOA (2000), PFHxS (2004) and PFNA (2010), while upward–upward trends were observed for PFUnDA (1984) and downward–upward trends were observed for PFTeDA (2004), PFBS and PFHxA (2011) (Table 2, Fig. 4 and S3, ESI†). No trend or change-point was observed for PFHpA and PFDoDA, but for 10 and 11 years (respectively) out of 17 all samples were below LOQ. PFNA and PFDA showed similar increasing trends in pooled blood serum samples from nursing women living in Uppsala. In that study, serum PFHxS increased over the entire monitoring period (including the most recent years). In contrast, PFHxS in milk from the present work showed a significant decreasing trend from 2004 and onward. In 2012 some of Uppsala’s drinking water supply was found to be contaminated with PFASs, most likely originating from firefighting foams used at a military airport just outside Uppsala. PFHxS was one of the substances found in high levels in the drinking water; consequently, ongoing PFHxS contamination could explain the absence of a decrease in concentrations in that area. In contrast, decreasing trends (1995–2010) for FOSA, PFOA and PFOS concentrations were reported in human serum from Uppsala, consistent with our observations in milk and with the phase-out by 3M.

There was a clear shift in PFAS pattern (PFOA, PFNA, PFDA, PFUnDA, PFHxS, Br-PFOS, L-PFOS, PFDS, L-FOSA) over the study period (1972–2016) in Stockholm (Fig. 2A). Before 1996 the PFAS pattern was dominated by Br-PFOS, L-PFOS and L-FOSA; since then the concentrations of these substances have decreased, while concentrations of PFUnDA, PFDA and PFDS, have increased (samples from 2013–2016). This change in pattern may be due to the large historical production of PFOS and PFOS precursors before 2000, which was followed by ongoing contemporary production of long-chain PFCAs and PFCA precursors. Differences in the environmental fate and/or elimination half-lives of individual PFASs may also influence trends observed in humans. The centers of gravity for the three time periods were all significantly different (repeated Hotellings T2 test, p< the Bonferroni adjusted a value of 0.0167). The shift in PFAS pattern over time in milk from Stockholm is consistent with a shift in pattern reported previously in blood samples from Uppsala over a slightly different time period.

**Estimated daily intakes and potential health risks**

The upper- and lower-bound PFAS concentrations measured in maternal breast milk were used to determine the estimated daily intake (EDI) of individual and ∑PFASs via breast milk (Tables S8 and S9, ESI†). For these calculations an infant body weight of 7 kg and a milk consumption rate of 600 mL per day were used, as described in Kärman et al. Lower bounds estimates ranged from 7.1–40 ng per kg body weight per day (ng/kg bw/d) in Stockholm and from 5.3–25 ng/kg bw/d in Gothenburg, while upper bounds estimates ranged from 9.7–42 in Stockholm and 7.7–27 ng/kg bw/d in Gothenburg. In comparison, Winkens et al. estimated a ∑PFAS EDI of 29 ng/kg bw/d for milk sampled from Sweden in 2004 and 43 ng/kg bw/d for milk sampled from Spain in 2008, while Tao et al. estimated an EDI of up to 87 ng/kg bw/d for milk collected in the U.S. in 2004.

Whether or not these EDIs represent a significant health risk for infants is a source of debate. Winkens et al. pointed out
Table 2  Summary of trends for detectable PFASs over the total study period (and last 10 years period for Stockholm) (in %) assessed from the annual means (pg mL\(^{-1}\)) in human milk from Stockholm and Gothenburg. \(P\) value: YRQ: years required to detect an annual change of 10% with a power of 80%; LDT: lowest detectable trend (% per year) for a 10 years period with the current between-year variation at a power of 80%. Last year’s concentration is estimated from the smoothed trend. Numbers in brackets are 95% confidence intervals (C.I.). The total number of samples and years \(N\) for each time-series are shown in columns three and four.

that the tolerable daily intake (TDI) for PFOS and PFOA set by EFSA (150 and 1500 ng/kg bw/d, respectively) are up to two orders of magnitude higher than the minimal risk levels (MRL) set by the Agency for Toxic Substances & Disease Registry (30 and 20 ng/kg bw/d, respectively). Notably, none of the EDIs determined here for PFOS or PFOA exceeded these levels, even using upper bounds estimates. However, the aforementioned TDI and MRL only consider single substances; safe levels for most of the PFASs measured in the present work have yet to be defined and few data are available on the risks associated with
Fig. 4  Temporal trends of FOSA (sum isomers), PFBS, PFDA, PFDoDA, PFHxA, PFHxS, PFNA, PFOA, PFOS (sum isomers), PFTeDA, PFTrDA and PFUnDA (pg mL\(^{-1}\); y-axis) in human milk from Stockholm (1972–2016; x-axis). Curves represent significant (p < 0.05) linear (red), non-linear (dashed purple) and change-point (blue) trends. Grey bars represent years where all values were <LOQ. Error bars (95% C.I.) are shown for years where there are individual samples.
Table 3 Change-point detection for detectable PFASs assessed from the annual arithmetic means (pg mL⁻¹) in human milk from Stockholm 1972–2016. NY is the total number of years for the various time-series, P(trend) shows the p-value for the log-linear regression, P(CP) shows the p-value for the change-point, year(CP) is the year when the CP occur, b(1), (2) are the slopes of the first and second regression line which also is equal to the average annual percentual change in concentration, P(1), (2) the p-values for the first and second regression line and LOQ/NY show number of years were all samples were below the level of quantification (LOQ).

Confounding factors
In studies where PFAS concentrations are affected by confounding factors (e.g. age or parity) it is possible to adjust the concentrations for these confounders to lower the variation within the samples. A multiple regression analysis showed no significant correlations between age (parity was not included in the multiple regression since all mothers from Stockholm in 2012 were primiparous) and concentration for any of the PFAS analyzed in Stockholm 2012. Correspondingly the PFAS concentrations in samples from Gothenburg in 2012 did not show any significant correlations with either age or parity, with the exception of Br-PFOS which was significantly negatively correlated with age (p < 0.019). The adjustment of Br-PFOS concentrations with age improved the coefficient of variation (CV) from 77% to 54% [Fig. S4, ESI]. This is in contrast to the pattern seen for most fat soluble POPs, in which concentrations in milk tend to increase with age.22 To reduce the influence of confounding factors the sample definition in the sampling program is narrow, the mothers are of similar age and most of them are primiparous. Thus, the range of the age (Stockholm and Gothenburg) and parity (Gothenburg) were small, which reduces the likelihood of finding significant correlations with concentration.

Conclusions
While the concentrations of several PFASs have declined in human milk in recent years, others continue to increase, presumably due to ongoing commercial use. These divergent time trends have resulted in a shift in the PFAS profile in human milk over the last 5 years compared to 2000–2012 and pre-2000. As few data are available on the effects of cumulative PFAS exposure, the impact of this ‘new’ profile on the risks to infant health remain unclear. With this in mind, hazard assessments involving simultaneous exposure to multiple PFASs in relative proportions consistent with those observed in human milk would improve overall risk characterizations, and predictions of the potential health impact of shifting PFAS profiles over time.

Conflicts of interest
There are no conflicts to declare.
