Toward computational and experimental characterisation for risk assessment of metal oxide nanoparticles

Laura Escorihuela, ^a Benjamí Martorell, ^{*a} Robert Rallo ^b and Alberto Fernández ^a

Metal oxide (MeO) nanoparticles (NPs) have become common in our everyday life over the past years. However, there is still an important knowledge gap regarding their toxicological effect and, in particular, how the different physical and chemical properties of MeO NPs influence their cytotoxicity and the subsequent implications for risk assessment. This work analyses the physicochemical properties of MeO NPs that have been reported as relevant for risk assessment and the experimental and theoretical methods used to obtain them. The surface, physical and chemical properties of NPs have been critically revisited to shed light on the features that can cause toxicity. Due to the large number of existing MeO NPs, *in silico* studies are necessary to get a good understanding of the NPs' physicochemical properties; therefore this review focuses on the state of the art computational methods used to model MeO NP toxicity: QSAR and QSTR models and their alternative approaches provide a better understanding of MeO NP biological toxicity in organisms.

Environmental significance

The use of nanoparticulate materials has exponentially grown during this decade due to their extraordinary properties, covering a wide range of products in the opto-electronics, pharmaceutical, medical, cosmetic and textile industries. However, the risk to human health (cytotoxic, mutagenic or carcinogenic effects) for most of them is still not well established. Alternative routes for risk assessment based on *in silico* methods avoid the highly expensive and time-consuming toxic evaluation of nanoparticles in the laboratory. Cheminformatic tools relate physicochemical properties with the cytotoxic effects, but standardised methods are missing. Therefore, the establishment of standard properties and mathematical models to predict toxicity is necessary for a more efficient assessment of nanoparticles.

1. Introduction

The Nobel prize awardee Richard Phillips Feynman, with his famous sentence in 1959 stating that “there's plenty of room at the bottom”,¹ was the first to envisage the potential of nanoscale materials for the global progress of industrial society and technology. In Europe, nanotechnology is considered as a key enabling technology (KET) that provides the basis for new advances and innovations in many fields of science and technology. In terms of economic impact, the global market of nano-enabled products was valued at \$26 billion in 2014 and is expected to reach about \$64.2 billion by 2019.²

Particles with one or more of their dimensions in the range of a few nm up to tenths of μm have different properties, effects and behaviour relative to their microscale counterparts.³ Recent studies provided more insight on the size

dependence of nanoparticle⁴ properties and reactivity, revealing that small sized nanoparticles (NPs) have a more variable behaviour in terms of their properties than larger size NPs, which have a more constant behaviour. For example, size dependence changes in NPs below 5 nm have more influence than changes in NPs in the range of 15 to 90 nm due to the quantum size and macro-quantum tunnelling effects.⁵ Another relevant effect of the smaller NPs is the direct exposure in an organism *via* the mechanism of entering directly inside the body and dissolving and delivering the toxic metal, described as the Trojan effect. This effect is specific for nanoscale particles given the inadvertent recognition by cell receptors.⁶

Due to their intrinsic properties, nanomaterials (NMs) are the cornerstone of a wide range of technologically advanced applications, with metal oxide (MeO) NPs being the most used in areas such as electronics, optics, opto-electronics, pharmacy, medicine, cosmetics and textiles.^{1,5} NPs are becoming more and more common in many consumer products; however there is still an important knowledge gap regarding how size influences their physicochemical properties

and, in turn, their toxicity.^{7,8} For instance, at the nanoscale, several metal oxides are toxic, whereas they do not show any significant toxicity at the microscale.⁹ In 2006, Nel *et al.* described the mechanisms used by NMs to interact with biological systems and their toxicological effects; since then, their total comprehension has not been achieved yet.⁶

Therefore, NMs need a specific regulation to assess their toxicity. In the EU, the REACH¹⁰ (Registration, Evaluation, Authorisation and Restriction of Chemicals) agency directive is the current regulatory framework for chemical risk assessment and management. NMs are considered as independent “chemical substances” and therefore their registration and labelling are also regulated. The EU acknowledges that the application of REACH may cause administrative burden, affect time to market and increase marginal costs of nano-enabled products and technologies. In the United States, the Environmental Protection Agency (EPA) has a special regulation for NMs, the Toxic Substances Control Act (TSCA). NMs are referred to in TSCA as chemicals at the nanoscale. Due to their increased use in a huge range of products, in 2015 the TSCA regulation was extended to include chemical substances manufactured or processed as nanoscale materials (<https://www.epa.gov/reviewing-new-chemicals-under-toxic-substances-control-act-tsca/control-nanoscale-materials-under>).

Nonetheless, toxicity assessment of NMs is a daunting task that involves multiple testing conditions and endpoints, and testing of different NP configurations (*i.e.*, different combinations of core, shell and functionalization layers, *etc.*). *In silico* testing, specifically the establishment of quantitative (nano)structure–activity relationships (QNARs), nano-quantitative structure–property relationships (nano-QSPRs) or quantitative structure–toxicity relationships (QSTRs), constitutes a cost-effective approach to fill the existing gaps in nanosafety data. The establishment of nano-QSPRs and QNARs requires (i) a detailed physicochemical and biological characterization of NMs and (ii) the development of computational nano-descriptors suitable to represent the electronic, atomic and molecular structures of NMs.

The development and validation of standard protocols for the experimental and theoretical characterization of NPs is fundamental to the generation of the high-quality data required to develop reliable nano-QSPRs and QNARs. Several reference descriptions of experimental and theoretical research protocols have been published by the Organisation for the Economic Cooperation and Development (OECD).¹¹ In addition, the Nanosafety Cluster,¹² promoted by the EU commission, helps to monitor and harmonize the European activities related to the risk assessment of NMs.

Recent results have described mathematical models linking NM structure descriptors with toxicity effects. These descriptors include physical and chemical properties such as electronic band gap, or surface properties such as surface formation energy or reactive sites.^{8,13,14} Regarding this relationship, for example, a band gap descriptor can be used to estimate the oxidative stress of MeO NPs.¹⁵ Recent studies separate the surface modifiers of NPs from the core of a MeO

for predicting cellular uptake.¹⁶ In particular, QSAR models show that diverse combinations of NP properties can be used to classify different levels of biological response for ZnO and TiO₂ NPs.¹⁷

Regarding the use of theoretical testing methods, REACH promotes the use of computational methods to implement 3R (replacement, reduction and refinement) approaches aimed at reducing and ultimately avoiding animal testing. Furthermore, REACH considers a “chemical element obtained by any manufacturing process, including any impurity deriving from the process used”. Any chemical element can be classified within different levels of impurities if it provides hazardous properties. Therefore, REACH forces NP producers and importers to provide toxicological data and environmental impact assessments (*e.g.*, environmental exposure) when the NP concentrations are lower than 0.1% in weight. The effective implementation of REACH regulations requires the development of alternative non-testing methods (*e.g.*, QSAR) to evaluate the toxicity of nanoparticles.

This review discusses relevant physicochemical properties of metal oxide nanoparticles and their implications for *in silico* nanotoxicity assessment of MeO NPs based on OECD recommendations. It is focused on the description of special properties of MeO NPs, their implications for risk assessment and their use in nano-QSAR and nano-QSPR methods for toxicity prediction. Finally, potential future research directions and challenges are discussed.

2. Metal oxide nanoparticles

MeO NPs are widely used in many technological applications such as semiconductors, capacitors, coatings, solar cells, *etc.* because of their highly efficient properties due to their limited size and high density of corner or edge surfaces, that result in unique optical, chemical sensing, and semiconducting properties. However, the high diversity of MeO and sizes of NPs and the lack of standardized measurement protocols hinders the use of physicochemical parameters for risk assessment.

Bulk oxides are stable in a well-defined solid crystallographic structure (or a few structures, in some cases) under standard conditions. However, for smaller sizes (*e.g.* microscopic scale), the lattice stress must be taken into account because it can affect the structural properties up to the total disappearance of the crystallographic structure at the NP limit. Accordingly, phases with low stability in bulk form can be found at the nanoscale. This structural phenomenon has been reported for TiO₂, VO_x, Al₂O₃ and MoO_x oxides.⁶

Nanoparticle size also influences other important features of electronic and physicochemical properties such as electrical conductivity and colour. At the nanoscale, semiconducting materials become metallic and non-magnetic particles become magnetic due to quantum-size and macro-quantum tunnelling effects. From the point of view of solid-state physics, both the superposition of bulk states and the increase in the material strength may affect electronic properties such as the band gap.

This section discusses and analyses the physicochemical properties of NPs, identified by the OECD¹⁸ as relevant for risk assessment, that are affected by the size or by the special reactivity of MeO NPs.

2.1. Surface properties

Surface properties play an important role in many aspects of material applications. Top layers of atoms in surfaces come into direct contact with their surrounding environment. Based on their applicability to risk assessment, surface properties and reactivity are considered as key nanoparticle features in the OECD test guidelines.¹¹ Surface properties are influenced not only by the external layer of atoms but also by some internal layers.

Surface formation energy. One of the main changes at the nanoscale, relative to the macroscale, is the significant increase in the fraction of atoms that lie on the nanoparticle surface with respect to the total number of atoms that form the whole material (Fig. 1). This is an important factor that changes the surface reactivity and the behaviour of this nanosurface relative to an equivalent microscale surface.

Surface atoms are not completely coordinated with respect to the interior atoms, and therefore they show a higher energy and reactivity than the fully coordinated ones. The extra energy at the surface, γ , is defined as the free energy necessary to create a new unit of area:¹⁹

$$\gamma = \left(\frac{\delta G}{\delta A} \right)_{T,P} \quad (1)$$

where A is the surface area, G is Gibbs' free energy, T is the temperature and P is the pressure. In the case of surface growth, the extra energy required to create the surface and stabilize the surface atoms in their new atomic positions is equal to:

$$\gamma = \frac{1}{2} N_b \varepsilon \rho_a \quad (2)$$

where N_b is the number of broken bonds, ε is the bond strength, and ρ_a is the surface atomic density, *i.e.*, the number of atoms per unit area.

Fig. 1 Comparison of the percentage of atoms exposed on the surface at macro and nano scales. Adapted from the book *Science at the Nanoscale*.¹⁹

Surface charge. Surface charge is a physicochemical property of NMs that controls the dispersion and aggregation of engineered NMs and affects cellular uptake.²⁰ Surface charge is related with the partially saturated bonds on the surface and the partially filled d-orbitals of metal atoms and p-orbitals of oxygen atoms. This property may determine binding sites for receptors, affect the dispersion and aggregation of particles, and affect the capacity to generate reactive oxygen species (ROS; more details are given in section 2.3). For example, stable metal oxides do not show toxic effects, although metallic NMs that have a redox potential may be cytotoxic and genotoxic.³ Heavy metal ions may induce oxidative stress, inflammatory responses and electron-hole pair generation during photo-activation, leading to free-radical generation.²¹

Zeta potential. This is a universal feature of particles, consisting of the measurement of the electrostatic interactions between dispersed particles. The zeta potential is a key NP feature that governs cell biological inactivation and cell adhesion. Zhang *et al.* proposed a theoretical model based on this property to predict the interaction of iron oxide NPs with normal and cancer human breast epithelial cells.²²

From the perspective of nanoparticle characterisation, surface charge is usually reported as the zeta potential, which includes the electric potential in the interfacial double layer and the pK_a of the particle.²⁰ As a consequence, this property is a good toxicity predictor for low-solubility NPs, and it is considered by the OECD as a relevant parameter for fate and exposure evaluation.²² Results have confirmed that the zeta potential is affected not only by suspension conditions such as pH, temperature, ionic strength and the types of ions in suspension²³ but also by intrinsic particle properties such as size and concentration. Nevertheless, these data are not always well reported in the bibliography, given that sometimes the variability of the experimental process is not described in detail.²⁴

The zeta potential is usually measured using particle size analyzers based on laser Doppler electrophoresis. The zeta potential, ζ , is calculated from the measured electrophoretic mobility, μ , through Henry's approximation:²³

$$\mu = \frac{2\varepsilon_0 \varepsilon_c \zeta f(kr)}{3\eta} \quad (3)$$

where ε_0 is the permittivity of a vacuum, ε_c is the permittivity of the medium, k is Debye-Hückel's parameter (or reciprocal double layer thickness), r is the hydrodynamic radius of the particle, η is the viscosity of the medium, and $f(kr)$ is Henry's function. The Debye-Hückel parameter, k , is calculated as:

$$k = \left(\frac{2000F^2}{\varepsilon_0 \varepsilon_c RT} I \right)^{1/2} \quad (4)$$

where F is Faraday's constant, R is the gas constant, T is the temperature, and I is the ionic strength in the solution.

The influence of pH on the zeta potential is explained by the protonation/deprotonation of oxides and metal centres on the surface groups of the MeO NPs. MeO NPs have a positive zeta potential in acidic environments, whereas in basic environments the property has negative values.²² For example, in the case of bare TiO₂ at pH 6.0, ζ increases from 6.7 to 8.2 mV as the particle concentration varies from 0.5 to 5.0 mg L⁻¹.

Several studies also revealed that the zeta potential could depend on particle concentration.^{23,25} For example, as the particle concentration increases from 1.0 to 10.0 mg L⁻¹, the zeta potential of naked TiO₂ at pH 6.0 varies from 6.7 to 11.7 mV, and from 4.7 to 10.3 mV for Fe(OH)₃ NPs at pH 7.5. This effect, however, could be attributed to either a real effect or to an experimental artefact. Tantra *et al.*²⁶ suggested that the shift in ζ at low particle concentration of multi-walled carbon nanotubes, silica (LUDOX) and gold NPs, was due to an increase in the contribution of the signal from extraneous particulate matter. Small changes observed in zeta potential measurements at low particle concentrations indicate the adsorption of significant counterions from the solution on the particle surface. A possible counterion¹² could be the OH⁻ coming from the dissociation of water molecules, and the bicarbonate HCO₃⁻ and carbonate CO₃²⁻ from the reactions, due to the presence of carbon dioxide (CO₂) in solution from ambient gas. If the particle concentration is high, then the amount of adsorbed HCO₃⁻ can be neglected and the corresponding zeta potential becomes independent of the NP concentration.²³ Therefore, the above results indicate that care must be taken in choosing appropriate particle concentration conditions for electrophoretic zeta potential measurements under standardised conditions of temperature and pH.

2.2. Physical properties

This subsection summarizes the most relevant physical properties for MeO NP characterisation for toxicity assessment.

Chemical potential. The chemical potential (μ) is the driving force that leads to the formation of the NP in its final composition and shape. The chemical potential of an atom on a NP surface depends on the surface curvature radius as described by the Young–Laplace equation:²⁴

$$\Delta\mu = 2\gamma \frac{\Omega}{R} \quad (5)$$

where R is the radius of a nanoparticle with a spherical surface, Ω is the volume of the particle and γ is the surface energy.

The chemical potential of an atom on a NP surface is higher in convex surfaces (*i.e.*, with positive curvature) than in flat surfaces. Mass transfer from a flat surface to a convex one results in an increase of chemical potential, while the opposite occurs with concave surfaces.²⁴

As previously mentioned, the μ of a NP dictates its shape, composition, and crystallographic structure. At the nanoscale, free energy and stress can induce changes in thermodynamic stability, modifying cell parameters²⁷ and, as a consequence, causing structural transformations in the crystal structure of the NP with respect to the bulk.⁵ In other words, when mechanical and structural stabilities are balanced with free surface energy, then unstable crystalline bulk structures may become stable at the nanoscale. This phenomenon has been observed for MeO NPs such as TiO₂,²⁷ VO_x,⁵ Al₂O₃,⁵ and MoO_x.²⁸

The ionic or covalent character of metal–oxygen bonding is related to the chemical potential of the NP. Ionicity can be affected by the NP size. The increase in ionic character is inversely proportional to the size of the particle²¹ and has direct effects on properties such as conductivity and chemical reactivity.^{29,30} In addition, the toxicity of NPs is strongly related to the electrostatic potential since NP–cell interaction mechanisms depend on electrostatic forces. Positive NPs are electrostatically attracted by negative bacterial membranes, where they can be absorbed (only this electrostatic type of interaction has been found experimentally).²⁹

Optical properties. Optical properties are amongst the most important properties for development of new technological devices based on metal oxide nanoparticles. Optical properties are usually determined by electronic transitions within the material that can form electron–hole pairs in the electronic structure as well as light scattering effects in the solution. Due to Coulomb's interaction, the electrons and holes existing in a material are known to form excitons, whose properties are fundamental to understanding the optical nature of semiconductors. The distance between the electron and the hole is known as the Bohr's radius of the exciton. Typical exciton Bohr's radii of semiconductors are on the order of a few nanometres.³¹ In bulk semiconductors, excitons can move freely in all directions. When the length of a semiconductor is of the same order as the exciton radius, *i.e.*, a few nanometres, a quantum-confinement effect occurs and the properties of the exciton are modified. Depending on the dimension of the confinement, three types of structures can be defined: quantum wells (QWs), quantum wires (QWRs), and quantum dots (QDs). In a QW, the size of the material is reduced only in one direction and the exciton can move freely in the other two directions. In a QWR, the size of the material is reduced in two directions and the exciton can move freely in one direction only. In a QD, the size of the material is reduced in all directions and the exciton cannot move freely at all. In these confined structures, the exciton nature is modified and novel optical properties emerge. For a nanoparticle of radius R and a Bohr's radius of the bulk R_b , there are three possible confinements: (1) weak confinement ($R \gg R_b$), (2) intermediate confinement ($R \approx R_b$), and (3) strong confinement ($R \ll R_b$).³² The effective mass approximation theory³³ explains the above effect for nano-semiconductors, but other theories exist such as the free exciton collision model (FECM),³⁴ which is based on the length of the bond

versus its strength. Both theories explain that band gap energy is inversely proportional to the primary size of a particle when quantum-size effect dominates the confinement.

On the other hand, the conductivity of light is easily obtained by measuring the reflectivity and the absorption of solid materials. Reflectivity is a size-dependent property because it is affected by the size of particles and by the wave impedance of materials. As a result, nanoparticles are good candidates for developing high-performance optoelectronic devices such as semiconductor light-emitting diodes and laser diodes when the size is decreased as in the case of ZnO.³⁵

Optical band gap. This property can be measured by UV-visible spectroscopy. The optical band gap, E_g , can be estimated by Tauc's model³⁶ using the following equation:

$$(\alpha hv) = A(hv - E_g)^n \quad (6)$$

where A is a constant, hv is the incident photon energy, and α is the absorption coefficient, which can be calculated using Beer-Lambert's law.

In the case of ZnO NPs, a broad band in absorption spectra is observed at around 369 nm, characteristic for pure ZnO. Bulk ZnO has a direct band gap of 3.34 eV.³⁷ In the case of TiO₂ NPs, the band gap is 3.15 eV.³⁸

Electrical conductivity properties. MeO NMs can be ionic or covalent in terms of conductivity. According to Boltzmann statistics, electronic charge carriers are a function of the energy band gap and temperature, given the electronic conduction. Electronic conduction is referred to as n- or p-type, depending on whether the principal charge carrier is an electron or a hole. The number of free charges can be increased by creating more vacancies and creating non-stoichiometric effects in a NP. Simple and complex oxides based on the first transition metal elements give a huge variety of non-stoichiometric phenomena. Their origin is in the unfilled 3d electron shell.³⁹ Oxygen-deficient perovskites are a good example of such materials because their physical properties depend on the oxygen vacancy. Oxygen stoichiometry depends on the temperature and can be easily controlled by redox processes.³⁸ For example, thermal activation can move ions from side to side as an ionic mechanism for electrical conductivity. Four different mechanisms for ionic conduction have been observed: through direct exchange, using interstitial holes, through vacancies, and through the Grotthuss mechanism.⁴⁰ An example of these mechanisms is CeO₂ NPs, which show an n-type conductivity that is four orders of magnitude greater than the one corresponding to their crystalline structure. The higher conductivity is explained by the increase of the electronic contribution.⁴¹ Strong size dependence is reported for electrical conductivity in gas sensing devices such as SnO₂, WO₃, and In₂O₃.⁴² An interesting example of ionic conduction is found in Li batteries, whose conductivity has been enhanced, stressing the nanostructure of Li, creating nanopores and introducing Al₂O₃.⁴³

2.3. Chemical properties

Chemical reactivity properties are a key factor for the description of NP bioactivity and toxicity. Nanoparticle reactivity is determined by the chemical composition of the core and that of the surface and, if it exists (*i.e.*, not being amorphous), by the crystallographic structure of the NM. The three key parameters responsible for the high reactivity of nanoparticles are the coordination environment of surface atoms, the redox properties, and the oxidation of the surface layers.

Given their chemical properties, MeO NPs are widely used as absorbents and chemical catalysts.

Acid/base strength. The acid/base properties (or acidity from here on) of MeOs are correlated with the redox potential of the metal center⁴⁴ and the protonation and deprotonation of the oxygen atoms on the surface. Cations act as Lewis acids, lattice oxygen anions are basic, and surface hydroxyl groups can be both acidic (Brønsted site) and basic. The valence electrons of MeOs easily move, resulting in acid/base properties. Given that Lewis acidity is present in ionic oxides and almost absent in covalent oxides, Lewis acidity is generally correlated to the ionicity of the metal-oxygen bond. The stronger the Lewis acidity, the fewer the hydroxylated centres on the surface.⁴⁵ Examples of strong acid MeO NPs are Al₂O₃ and Ga₂O₃.³⁴

Most ionic MeO NPs show a weak Brønsted activity to protonate bases. Nevertheless, SiO₂, GeO_x and BO_x are exceptions to this rule⁴⁰ due to their low valence, with the strongest Brønsted acidity appearing in oxides with valences of five or higher (WO₃, MoO₃, V₂O₅ and S-containing oxides).⁴⁰

Finally, the isoelectric point (IEP) of NPs depends on the strength of the acid or base character of a material. In the context of toxicity, it has been reported that the IEP of TiO₂ NPs affects their antibacterial activity.⁴⁶

Solubility of metal oxide nanoparticles. Solubility in aqueous medium is strongly related to the bioavailability and toxicity of metal oxide nanoparticles. Accordingly, it has been considered by the OECD as a relevant parameter for fate and exposure during the toxicity assessment of NPs.¹⁸

The solubility of a compound in a solvent at a given temperature is not only a thermodynamic property of the bulk but also depends on the dimension of the compound. Usually, the solubility of NPs is estimated by using a correction of Ostwald's equation,⁴⁷ known as Freundlich's equation or Ostwald-Freundlich's equation:⁴⁸

$$x_{A(\beta)} = x_{A(\beta)}^0 \cdot \exp\left(\frac{2V_{A(\alpha)}^0 \cdot \sigma_{\alpha/\beta}^0}{RT r_\alpha}\right) \quad (7)$$

where $x_{A(\beta)}$ is the solubility of component A in the form of a spherical pure phase α of radius r_α in a given solution, at temperature T and at fixed pressure P . Analogously, $x_{A(\beta)}^0$ corresponds to an infinitely large phase α . $\sigma_{\alpha/\beta}^0$ is the interfacial energy between two (size-independent) phases, $V_{A(\alpha)}^0$ is the molar volume of pure phase A, and R is the universal gas constant. This equation has been used in materials science,

pharmaceutics, chemistry, and physics, but its applicability is highly controversial. Kaptay⁴⁹ enumerated the features of Ostwald's original equation⁴⁷ and eqn (7) as follows.

- Solubility is inversely proportional to size and independent of the surface area of the phase, following what Gibbs and Ostwald postulated.
- When size dependence on interfacial energy is taken under consideration, Ostwald's equation is correct.
- Numerical values from Ostwald's equation are similar to those from Ostwald–Freundlich's equation, showing that size dependence on solubility increases when dissolved particles have poorer “wettability” in the solution.

The use of *in silico* simulations provides an alternative approach to evaluate the solubility of MeO NPs. Recently, Escorihuela *et al.* have developed a method based on density functional tight binding models for evaluating qualitatively the solubility of NPs in aqueous solutions. This methodology was applied to ZnO NPs in water, although it can be easily transferred to other materials and solvents.⁵⁰

For partially soluble MeO NPs, toxicity is also attributed to the release of free metal ions into the solution. Examples are ZnO and CuO,⁵¹ where toxicity cannot be satisfactorily explained only by the solubility of the NPs. Furthermore, the biological response can be modified depending on the kinetic effects of solubility; after 24 hours most of the metal ions and the aggregates are dissolved. That is why metal ion release is considered as one of the most important factors for toxicity assessment.⁵²

Reactive oxygen species (ROS) generation. Nanoparticle surfaces act as active sites in the catalytic generation of ROS; therefore, although ROS are not a direct physicochemical parameter of MeO NPs, they are a consequence of NPs and their toxicity is then correlated to NPs. *In vitro* studies showed the relationship between ROS formation and toxicity effects.²³ Therefore, the OECD considers ROS to be an endpoint related to the surface reactivity of NPs.⁵³

ROS generation can be toxic both outside and inside cells. Metal ions released from NPs can enter cells and cause toxic effects such as oxidative stress, which impacts cell viability and may ultimately result in cell death. Extracellular ROS can also induce a series of oxidative stress reactions. For instance, the presence of OH radicals formed on MeO NPs due to ultraviolet (UV) radiation is a strong antibacterial mechanism²⁶ present in a range of materials with a wide band gap such as ZnO.⁵⁴

ROS generation is a problem not only in cytotoxicity but also in other fields of science. For example, MeO NPs can create defects in polymer electrolyte membranes (PEMs) used in fuel cells. The addition of non-stoichiometric ceria NPs induces effectively ROS generation during fuel cell operation, with the consequence of less operability duration and a degradation of the PEM.⁵⁵

Experimental detection of ROS is done by using luminescent probes and electron spin resonance (ESR) spectroscopy. Since direct examination of the ability of NMs to generate ROS has very poor selectivity and poor photostability due to the short life of ROS, it is necessary to use spin trap mole-

cules in both methods. For instance, dimethyl sulfoxide (DMSO) or 2',7'-dichloro-fluorescein diacetate (DCFH-DA) is used for ROS trapping. However, this method is not selective for different species since the scavengers do not selectively trap different ROS and it is difficult to distinguish, for example, the signal corresponding uniquely to OH radicals.⁴⁵

A common problem in these two methods is that some MeO NPs, such as TiO₂, have photocatalytic activity. Under illumination conditions, photocatalytic degradation of the spin trap may occur, giving a decrease in UV signal intensity against time. It is also difficult to obtain reproducible ROS spectra when nanoparticles do not form stable suspensions. In spite of this, ESR is a very stable and powerful method for the experimental characterisation of ROS.

3. Risk assessment

The risk assessment of bulk chemicals is usually performed as a three-step workflow including⁵⁶ (1) exposure assessment (determining the exposure magnitude, frequency and duration in populations); (2a) hazard assessment (including hazard characterization, dose–response in organs, tissues, cells and toxicity mechanism); (2b) hazard identification (relevant properties producing the adverse effect); and (3) final risk quantification based on likelihood of exposure and hazard.

Similarly, exposure and hazard are key factors that determine the risk that nanoparticles pose to the environment and humans. The physicochemical properties of MeO NPs contribute to their exposure and hazard profiles. Due to the large number of possible MeO NP combinations (*e.g.* size, shape, chemistry and surface modifications), performing a complete risk assessment for each nanoparticle would require significant time and resources.⁵⁷ Despite the large diversity and complexity of the MeO nanoparticle, space detailed experimental studies including *in vitro* assays using bacteria cultures, *in vivo* experiments using rodents,^{58,59} and NP uptake mechanisms have started to provide data to elucidate relevant cytotoxicity mechanism. Burello and Worth⁶⁰ proposed a theoretical model to predict the oxidative stress potential of oxide nanoparticles by comparing the redox potentials of relevant intracellular reactions with the energy structure of oxides. Horie *et al.*⁶¹ reviewed the cellular response of several manufactured NPs, giving special attention to MeO NPs. It was reported that MeO NPs induced an increase in the level of cell oxidation (ROS level).⁶² Comparing the results of experiments in human lung carcinoma A549 cells exposed to CuO, TiO₂, ZnO, CuZnFe₂O₄, Fe₃O₄, and Fe₂O₃ NPs showed that the intracellular ROS level was highly increased in the cells exposed to CuO nanoparticles. The opposite effect was observed in cells exposed to CeO₂ NPs in an oxidant stress test, induction of oxidative stress and anti-oxidative activity. These discrepancies are explained by the activation of antioxidative responses in cells or because the physicochemical characteristics of CeO₂ NPs were different in each experiment; therefore, no standardisation in the characterisation activity of NPs evidences opposite results in assays.

Broadly speaking, toxicity (*i.e.*, the potential of a substance to cause adverse health effects) is measured with respect to three parameters: dose, dimension and durability.¹⁵ In the case of NPs, the properties that induce specific toxicity effects and the mechanisms that mediate the adverse effects are still largely unclear.

As a consequence, many questions still remain open in terms of NP risk assessment. For instance, the UK government has requested advice from the Royal Society and the Royal Academy of Engineering to create a group of experts in nanoscience and nanotechnology. Similarly, in the USA, the National Nanotechnology Initiative was created to settle the innovations in this field. Worldwide institutions including the Organization for Economic Cooperation and Development (OECD), European Commission (REACH and Nanosafety Cluster), European Food Safety Authorisation, and Environmental Protection Agency also provide guidance for hazard assessment and risk evaluation of NPs.⁷ To date, the OECD has included in its Sponsorship Programme for Testing of Manufactured Nanomaterials a list of parameters, measurements, methods and endpoints which are considered as relevant for the regulation of NMs [ENV/JM/MONO(2006)19].¹⁸ Endpoints were categorized according to the state of dispersion, aggregation of NPs, size, surface area, porosity and surface reactivity. The document groups NPs into 11 categories of NMs and analyzes 24 different physicochemical test methods including physical identification, particle size distribution, shape, aspect ratios, agglomeration and aggregation, porosity, surface composition, crystal structure, and surface charge and reactivity. In addition to the above physicochemical properties, parameters for fate and exposure assessment such as zeta potential, water solubility and dustiness were also analysed. However, the only recommendations at this point are the use of harmonized methods and control of measurement conditions. In addition, it is necessary to develop guidance for developing NP descriptors, emphasizing the order of each descriptor and how to identify them in each technique, determining if the available information, even in the literature, is adequate and reliable.

In this context, computational (*i.e.*, *in silico*) methods have emerged as an alternative for the evaluation of physicochemical properties of MeO NPs. *In silico* approaches provide the basic framework to implement intelligent testing strategies for hazard assessment of nanomaterials. The use of data-driven approaches to establish relationships between the structure of a nanoparticle and its physicochemical properties and bioactivity profile is an effective tool for the *in silico* hazard assessment.

4. Development of nano-QSARs and nano-QSPRs for MeO NPs

Methods based on structural similarity principles such as quantitative structure–property relationships (QSPRs) and quantitative structure–activity relationships (QSARs) are well-established and play a central role in the prediction of the

properties and activity of bulk chemicals. The basic purpose of QSPR and QSAR is to correlate structural features (*i.e.*, descriptors) with physicochemical properties or activity (*e.g.*, toxicity), respectively. Descriptors can be developed from experimental measurements or calculated using computational chemistry methods. In general, the use of descriptors obtained *via* computational approaches is more effective than the use of experimental measurements since these calculations can be more easily extended to a much larger group of chemicals.

When we extrapolate these methods to nanostructures, the terms nano-QSAR and QNAR (quantitative nanostructure–activity relationship) modelling are preferred.¹⁶ However, the extrapolation of these techniques to nanoscale materials is not straightforward. The main factors that hinder the development of nano-QSPRs and nano-QSARs are data scarcity, computational cost of developing descriptors representing the whole nanostructure, and the limited knowledge of the mechanisms that regulate nano-bio interactions. The most relevant features describing NPs include particle size, size distribution, crystal structure, shape, chemical composition, surface area and chemistry, and electronic properties.⁶³

The properties of pristine nanoparticles (*i.e.*, as synthesized) usually experience drastic changes and dynamic behaviour under exposure conditions (*e.g.*, biological milieu). For instance, using the primary size of a nanoparticle as a predictor variable or as the basis to compute nanoparticle descriptors may be misleading or uninformative since the initial nanostructure of the pristine material could be completely different from the structure that emerges after exposure (*e.g.*, formation of large aggregates and attachment of proteins to the NP surface). An additional confounding factor is that structurally similar nanoparticles may interact with biological systems through various mechanisms mediated by different biological receptors. As a consequence, completely different sets of properties and descriptors can be identified as the most predictive for nanoparticles with similar structure. All the above factors should be taken into account when developing nano-QSARs and nano-QSPRs.

4.1. Examples of nano-QSARs/QSPRs

This subsection provides a brief discussion of nano-QSPRs/QSARs developed using descriptors related to the properties discussed in section 2.

One of the first attempts to develop a model was performed by Puzyn *et al.* using descriptors obtained from quantum chemistry calculations. The model was developed using a linear regression approach (eqn (8)) to predict *in vitro* toxicity for *Escherichia coli* bacteria:⁸

$$\log(\text{EC}_{50})^{-1} = 2.59 - 0.50\Delta H_{\text{Me}^+} \quad (8)$$

where ΔH_{Me^+} is the enthalpy of formation of a gas cation having the same oxidation state as the MeO structure, and EC_{50} is the effective NP concentration that inhibits 50% of bacterial population growth.

Using a similar approach, Gajewicz *et al.* developed a nano-QSAR based on multilinear regression to predict the toxicity of metal oxides:⁶³

$$\log(\text{LC}_{50})^{-1} = 2.47(\pm 0.05) + 0.24(\pm 0.05)\Delta H_{\text{fc}} + 0.39(\pm 0.05)X^c \quad (9)$$

where LC_{50} is the lethal concentration that causes mortality in 50% of the assay organisms/bio-indicators, ΔH_{fc} is the enthalpy of formation of a MeO nanocluster representing a fragment of surface, and X^c is the Mulliken's electronegativity of the cluster.

Mikolajczyk *et al.*⁶⁴ implemented a nano-QSPR model to predict the zeta potential using the correlation of two molecular descriptors: the spherical size, ϕ , and the weighted energy of the highest occupied molecular orbital (HOMO) for 15 MeO NPs:

$$\zeta = -11.26 - 4.46\phi - 2.39\varepsilon_{\text{HOMO}}/n\text{Me} \quad (10)$$

The model allowed one to quantitatively establish a relation between the zeta potential and the structural and electronic parameters of MeO NPs.

Recent development of new models for the simultaneous prediction of multiple toxicity endpoints gains importance as a comprehensive safety assessment, given the established toxicity of some NPs to both humans and the environment.⁶⁵ The application of perturbation theory goes one step beyond traditional QSAR approaches. Kleandrova *et al.*⁶⁶ used this tool on metal and metal oxide NPs. The aim was to make a QSAR model sensitive to modifications in NP compositions and experimental conditions. The descriptors used were molar volume, electronegativity, polarizability and NP size; in the case where a NM was formed by more than one element, these properties were normalized as the sum of the properties divided by the total number of atoms. Perturbation models aim to capture the sensitivity in the composition modification of the NPs *versus* experimental conditions and to determine if the variations in the structure and/or composition of NMs affect their toxicity. For these reasons, the original descriptors are modified by the moving average approach in order to create a new set of descriptors. Secondly, a set of pairs of NPs was created randomly wherein in each pair one particle was taken as a reference or initial state and the other particle was the predicted one. Perturbation theory was also applied by Luan *et al.*,⁶⁷ together with quantitative structure–toxicity relationship (QSTR) in metal and metal oxide NPs, to predict different cytotoxicity profiles considering changes in sizes and measurement conditions.

A more detailed review of existing nano-QSPR and nano-QSARs can be found elsewhere.⁶⁸

5. Conclusions

The evaluation of the toxicological effects of new materials plays a key role in the safe development of new products for general applications in electronics, cosmetics, optical devices, *etc.* In par-

ticular, NMs have shown an important increase in their applications, though their toxicity is still an open issue and several international organizations are trying to define and standardize methods to assess and control their hazardous effects.

Due to the large number of possible MeO NPs, an exhaustive experimental evaluation would take many years to complete and would require significant economic resources. *In silico* modelling of NMs is a clear alternative for obtaining, from computational chemistry calculations, descriptors that can be related to the properties and toxicity of NPs using QSAR, QSPR or QSTR methodologies, of which we have discussed a few examples here.

This review provides a detailed discussion on the physico-chemical properties that are considered to be the most relevant factors in the toxicity of NPs. Chemical properties and surface-related properties are the most crucial effects to describe the toxicity of NPs. Of particular interest are properties such as surface charge and pH-related effects as well as the solubility of nanoparticles and the subsequent shedding of metal ions that result in ROS formation on the NP surface.

5.1. Future works and research directions

The development of nano-QSARs and nano-QSPRs relies heavily on the volume and quality of available data. Although in the past years significant resources have been devoted to data curation and standardization, the information available for nanoparticles is still scarce relative to the information available for bulk chemicals and small molecules. As a result, current hazard models for nanoparticles have a limited applicability domain which restricts their use in regulatory risk assessment. Current data scarcity could be addressed by developing new high-throughput and high-content screening platforms for the rapid characterization of large nanoparticle libraries at multiple exposure conditions. Also, efficient computational approaches suitable for calculating whole nanoparticle descriptors are also required to provide the necessary structural information for model development.

Novel approaches to nano-QSAR/QSPR development are also needed. For instance, a specific area that requires further exploration is the development of probabilistic nano-QSAR/QSPR models based on probability density functions of descriptor values that match the size distribution of nanoparticle dispersions. Similarly, the integrated use of multiple modalities of data (*e.g.*, image data, numeric data and text data), both for the material and for the biological entities, could potentially open the door to model performance improvement.

In addition to assessing model performance, uncertainty quantification (UQ) and uncertainty propagation techniques should be included into the data-driven modelling workflows. Implementing proper uncertainty characterization schemes will contribute to informed decision-making during nanoparticle risk assessment.

As the amount of available data increases, data-intensive approaches such as deep learning can contribute to provide better linking between the structure of a nanoparticle and its

physicochemical properties and activity. One of the main advantages of deep learning is the ability to learn highly efficient data representations, making the process of feature selection unnecessary. In this context, the use of advanced techniques such as transfer learning should be explored as a potential way of leveraging existing data for bulk chemicals to bootstrap deep learning networks for nanotoxicity.

Regarding future directions for the toxicity evaluation, there is also an urgent necessity for the standardisation of the experimental tests to challenge and validate the results of modelling studies. It is necessary that this standardisation works together with computational and experimental methodologies to gain future insight into risk assessment and other challenges. The use of *in silico* methods and advanced machine learning techniques to obtain NP descriptors will provide in the future the next generation of basic tools to implement intelligent testing strategies for and to support the estimation of the toxicity risk assessment of nanoparticles and regulatory decision-making.

Conflicts of interest

There are no conflicts of interest for the authors to declare.
