Aqueous photo(electro)catalysis with eumelanin thin films†

Ludovico Migliaccio,† Maciej Gryszel, Vedran Đerek, Alessandro Pezzella and Eric Daniel Głowacki

We report that eumelanin, the ubiquitous natural pigment found in most living organisms, is a photocatalytic material. Though the photoconductivity of eumelanin and its photochemical reactions with oxygen have been known for some time, eumelanins have not been regarded as photofaradaic materials. We find that eumelanin shows photocathodic behavior for both the oxygen reduction reaction and the hydrogen evolution reaction. Eumelanin films irradiated in aqueous solutions at pH 2 or 7 with simulated solar light photochemically reduce oxygen to hydrogen peroxide with accompanying oxidation of sacrificial oxalate, formate, or phenol. Autooxidation of the eumelanin competes with the oxidation of donors. Deposition of thin films on electrodes yields photoelectrodes with higher photocatalytic stability compared with the case of pure photocatalysis, implicating the successful extraction of positive charges from the eumelanin layer. These results open up new potential applications for eumelanin as a photocatalytically-active biomaterial, and inform the growing fundamental body of knowledge about the physical chemistry of eumelans.

Conceptual insights

Melanins are biopigments ubiquitous in plants and animals. Thier unusual physical properties have made them the most-studied biomacromolecules in the context of (opto)electronic behavior. In recent years, the physical understanding of these complex materials has converged and melanins are playing an increasing role in emerging bioelectronic devices. In this article we present a completely different and previously unexplored aspect of melanin – its photocatalytic properties. We show detailed evidence that melanin performs as a classic semiconductor photocatalyst, participating in a true photocatalytic redox cycle of oxygen reduction and oxidation of various donors. While previous research has elaborated the possibility of photochemical generation of peroxide, and more recently the photoconductivity of melanin has been explained in detail, the discovery of true photocatalytic cycles being possible in melanin, including those featuring extraction of holes, is a novel conceptual insight. Our work represents a milestone in understanding the biomacromolecule melanin, and shows the wholly-new application of photo(electro)catalysts. This represents a major finding about melanins and opens up a new research direction of using biomolecules as potential photocatalysts for solar-to-chemical energy conversion, or harnessing this photochemistry for biomedical purposes.

Introduction

The electrical properties of biomolecules such as proteins, DNA, polysaccharides, and biopigments have attracted a growing amount of scientific interest in recent years. This attention is motivated by expanding fundamental understanding of the roles of eumelanins as photofaradaic materials. Deposition of thin films on electrodes yields photoelectrodes with higher photocatalytic stability compared with the case of pure photocatalysis, implicating the successful extraction of positive charges from the eumelanin layer. These results open up new potential applications for eumelanin as a photocatalytically-active biomaterial, and inform the growing fundamental body of knowledge about the physical chemistry of eumelans.

heteromacromolecule model versus the stacked oligomer model, where planar molecular units assemble via π–π stacking. The nature of the conductivity of eumelanin remains debated, though the recent consensus is that observations of macroscopic conductivity in eumelanin are primarily protonic in nature. Meredith et al. and Santato et al. have elaborated a charge transport model in a series of papers showing the relationship between protons as the major charge carrier and the paramagnetic species observed in eumelanin, with the phenomenon of photoconductivity in eumelanin also being accounted for in ref. 23. There are two distinct radical species in eumelanin, a carbon-centered and semiquinone one, with the latter being responsible for protonic photoconductivity and implicated in potential photochemical reactivity. Several devices exploiting protonic transport in eumelanin thin films have been demonstrated, though there is also evidence that there may be electronic charge carrier mobility in eumelanin in the form of hopping negative charges stored in the semiquinone structure. Eumelanin thin films can be electrochemically-addressed and intercalated with ions, thus they have been used in sodium ion batteries.

It has been recently demonstrated that some organic semiconducting small molecules can act as aqueous photocatalysts or photoelectrocatalysts for O₂ reduction to H₂O₂. A starting off question for this work is: can eumelanin be a bio-origin material with intrinsic photocatalytic activity? The photochemical properties of eumelanins have been studied in the biological context. Sarna et al. discovered the photochemical production of hydrogen peroxide via oxygen reduction during eumelanin autooxidation, inspiring detailed investigation into the role of eumelanin interactions with reactive oxygen species (ROS). In his 1990 paper, Sarna noted that the molar quantity of H₂O₂ produced during the photochemical degradation of eumelanin was 20% higher than the molar equivalent of the starting monomers. This foreshadows the possibility of a photochemical redox cycle where photogenerated electron donors (phenol, formate, and oxalate). The “blank” condition, referring to electrolyte alone, indicates that oxygen reduction to hydrogen peroxide, or proton reduction to H₂, can be accompanied by the autooxidation of eumelanin itself. If a photocatalytic redox cycle can be supported, more peroxide should be produced in conditions with added donors, and the eumelanin must show higher stability. The hypothesized photo-redox processes with eumelanin as a photocatalyst are illustrated in Fig. 1b. The two pH values were chosen since neutral pH is relevant to biological applications of melanin and also corresponds to the majority of existing experimental data on melanin photochemistry, and low pH was chosen to see if the proton-enhanced reaction of peroxide production (or hydrogen evolution) proceeded more efficiently. High pH conditions cannot be tested for photochemical experiments, as the eumelanin degrades in alkaline conditions.

Results and discussion

As a commonly-used standard eumelanin, we prepared synthetic eumelanin thin films by spin coating a 30 mg mL⁻¹ 5,6-dihydroxyindole (DHI) methanolic solution onto PET foil substrates followed by an ammonia-induced solid-state polymerization procedure (Fig. 1a). For photochemical experiments, eumelanin-coated foil circles were placed in solutions at two different pH values (pH = 2, pH = 7) in the presence and in the absence of different sacrificial electron donors (phenol, formate, and oxalate). The “blank” condition, referring to electrolyte alone, indicates that oxygen reduction to hydrogen peroxide, or proton reduction to H₂, can be accompanied by the autooxidation of eumelanin itself. If a photocatalytic redox cycle can be supported, more peroxide should be produced in conditions with added donors, and the eumelanin must show higher stability. The hypothesized photo-redox processes with eumelanin as a photocatalyst are illustrated in Fig. 1b. The two pH values were chosen since neutral pH is relevant to biological applications of melanin and also corresponds to the majority of existing experimental data on melanin photochemistry, and low pH was chosen to see if the proton-enhanced reaction of peroxide production (or hydrogen evolution) proceeded more efficiently. High pH conditions cannot be tested for photochemical experiments, as the eumelanin degrades in alkaline conditions (pH > 9).

We first conducted photolysis experiments by irradiation of eumelanin films in water under a pure O₂ atmosphere, using a solar simulator light source with an irradiance of 1.05 sun. (Fig. 2a). Aliquots of solution were periodically removed to test for the evolution of hydrogen peroxide using the tetramethyl benzidine/horseradish peroxidase (TMB/HRP) assay, well known from biological applications (see Experimental methods section and Fig. S1, ESI†). The results for hydrogen peroxide evolution over 12 hours are shown in Fig. 2b. Samples with added electron
photoconductivity,23,24 it follows that it may also be possible to
and considering that eumelanin has been reported to possess
photo-redox cycle in eumelanin (Fig. 1b).

(a) The experiment involves irradiating eumelanin films in an oxygenated
aqueous solution with a broad-spectrum light source and removing
 aliquots to determine H$_2$O$_2$ concentration. At the end of the experiment, the
film is removed and dissolved to determine the amount of degraded
eumelanin by measuring optical absorption. (b) The amount of evolved
H$_2$O$_2$ over time for conditions of pH 2 and pH 7, without donor (blank
case) and with readily-oxidizable donors oxalate, formate, and phenol.

Concluding that a photochemical redox cycle is possible,
and considering that eumelanin has been reported to possess
photoconductivity,23,24 it follows that it may also be possible to
have a photoelectrochemical catalytic behavior. In this case,
donors yield about twice as much peroxide as “blank” samples.
To quantify the difference between the contribution of eumelanin
autooxidation and the oxidation of donors, we calculated the
catalytic turnover number (TON) expressed as $n_{\text{mol}}$ of H$_2$O$_2$
generated/$n_{\text{mol}}$ DHI (starting indole equivalent) regarding a
simplified picture in which DHI acts as monomer and eumelanin
as its polymer, although the picture would be more complex.12
The quantity of degraded DHI is calculated from measurement of
the optical absorbance of the eumelanin in the film before and after
the entire process and comparing to the absorbance of
standard curves, as detailed in the Experimental methods
section. The TONS, along with max final [H$_2$O$_2$] values are given
in Table 1. The presence of donors increases the TON in all
cases, giving values 2-4 times higher than eumelanin alone
(autooxidation). This result confirms the presence of a true
photo-redox cycle in eumelanin (Fig. 1b).

Concluding that a photochemical redox cycle is possible,
and considering that eumelanin has been reported to possess
photoconductivity,23,24 it follows that it may also be possible to
have a photoelectrochemical catalytic behavior. In this case,

One can question which of these chromophoric species is respon-
sible for the photocatalytic processes. We measured the photoca-
thod current using a series of different narrow-band LEDs
details and chronoamperometric scans as shown Fig. S3, ESI†),
calibrated to the same irradiance, in order to construct a photo-
current action spectrum (Fig. 3c). These results show that at all
wavelengths where the eumelanin optically absorbs, a photocurrent is generated, and its magnitude follows the optical absorption of the eumelanin film. This behavior could be explained by a more complex picture in which there is a cooperative contribution of excited states of different potentials contributing to a single higher potential excited state as resultant after disproportionation/comproportionation reactions of different pigment constituents. In any case this finding indicates that all wavelengths where eumelanin absorbs result in photochemistry.

Despite the higher TON in eumelanin under oxygenated photocathodic conditions, it still degrades. The spectra obtained for pristine samples versus used samples, both as thin films (Fig. 3d), and after dissolution (Fig. 3e), confirm this. Neither the film nor the solution shows any additional peaks or otherwise changes in the shape of the spectra following irradiation. Only a monotonic decrease of each spectrum is seen, indicating that the eumelanin is uniformly degrading and not obviously producing another distinct chromophoric byproduct. Degradation proceeds as in the photocatalytic case from the action of unquenched positive moieties, holes, leading to autooxidation. It is possible that the action of accumulating H2O2 may also play an additional role in accelerating degradation as the photoelectrolysis proceeds and the concentration of peroxide increases.

In oxygenated electrolytes, the reaction of oxygen to hydrogen peroxide dominates. However, thorough deoxygenation of the electrolyte with argon for several hours followed by measurement under argon shows that a smaller photocurrent persists (Fig. 4a), on the order of 4–5 μA cm⁻². The photocurrent action spectrum follows the broad absorption of the eumelanin, exactly as in the oxygenated photocathode case (Fig. 4b and Fig. S3, ESI†). Sustained photocurrent in fully deoxygenated conditions can only be attributed to the hydrogen evolution reaction, where the photoexcited electrons reduce protons instead of oxygen. We find a relatively stable photocurrent over 32 hours. Over this time, the eumelanin film was found to degrade by the same amount as the oxygenated conditions gave after 6 hours. This indicates that despite the photocurrent density being about 70% of the oxygenated photocurrent, the eumelanin is about five times more stable (Fig. 4c and d). These photocurrent densities are too small to provide sufficient quantities of H2 for reliable quantification, however the only possible alternative hypothesis for the observed photocurrent is a degradation
reaction of the eumelanin itself, which is not consistent with the observation of substantially improved stability. From this we infer that the hydrogen evolution reaction is indeed occurring, albeit with very limited efficiency.

From our results it emerges that synthetic eumelanin can produce peroxide not only from autooxidation, as previously established, but also as part of a redox cycle where a donor molecule is oxidized, or where holes are neutralized by an electrode. This behavior is analogous to a classic semiconductor photocatalyst model, from the point of view of photochemical processes the semiconductor picture holds macroscopically. The mechanisms at play specifically in eumelanin are more complex, and still need to be resolved in detail. Sarna et al. have proven that eumelanin can perform a single-electron photo-reduction of oxygen to superoxide, which then becomes further reduced and protonated to yield peroxide. These findings however are for conditions of UV irradiation. We would speculate that with lower energy photons, as in our case, the superoxide mechanism may be surpassed by the thermodynamically-favored two-electron reduction of oxygen directly to peroxide. Our present results on photocathodic current are consistent with either the one-electron, two-electron, or coexistence of both pathways. Our observation of eumelanin-catalyzed photooxidation of various electron-donors, as well as the stabilizing effect of having an electrode injecting electrons into eumelanin photocathodes, highlights the important role of the photogenerated positive species on eumelanin. In the traditional semiconductor model of photocathodes, photoinduced electrons reduce a species in solution, while the corresponding holes are transported away to the electrode. Previous studies have established that protons are the positive charge carriers in eumelanin, while semiquinones carry mobile negative charges. This means that for eumelanin the photocathode model must be understood differently. A picture consistent with the prevailing knowledge on eumelanin is that photoreduction occurs, leaving behind a positive charge. This can be quenched by electron-carrying semiquinone species, which can be restored via injection of electrons from an underlying electrode. In the pure photocatalytic case, the positively-charged eumelanin moiety oxidizes electron donors directly. Our results confirm that oxygen accelerates photodegradation, and that in oxygen-free conditions a redox cycle involving hydrogen evolution is possible, with apparently better eumelanin stability.

Conclusions

These results are remarkable from the point of view of catalysis – eumelanin is a photocatalytic biomaterial capable of peroxide evolution, hydrogen evolution, and photooxidation of various organic substrates. This not only invites exploration in sustainability technologies with eumelanin as a bio-origin photocatalyst, but also has implications in the biological/bioelectronic sciences. Photodynamic therapies exploiting these photoprocesses in eumelanin are intriguing. Recently, eumelanin particles have been explored for photodynamic therapy which harnesses photothermal heating of the particles, however our results suggest that photofaradaic reactions could also be used to achieve various physiological effects. Mechanistic understanding must still be improved.

More detailed investigation of eumelanin photochemistry should be conducted to elucidate the role of one- and two-electron processes. Overall, our results open a new side of understanding of the physical chemistry of eumelains.

**Experimental methods**

**Eumelanin sample preparation**

All commercially available reagents were used as received and all the solvents were of analytical grade quality. Anhydrous solvents were purchased from commercial sources. 5,6-Dihydroxindole (DHI) was prepared according to a reported procedure. DHI thin films were prepared by spin coating with a Laurell WS-650MZ-23NPP/LITE coater on round PET foils of 3.14 cm² and on square FTO glasses of 3.75 cm² from concentrated methanol solutions (30 mg mL⁻¹) after filtering through a 0.2 μm Whatman membrane using a speed gradient of 2500 rpm for 30 s. Appropriate volume deposition (100–150 μL) was used. The DHI films then were chemically polymerized following the AISSP procedure: eumelanin thin films were obtained by exposing the DHI films (150–200 nm thickness) for 1 h to air-equilibrated gaseous ammonia from an ammonia solution (28% in water) in a sealed chamber at 1 atm pressure at controlled temperature (25–40 °C).

**Photocatalysis**

Eumelanin films were put in vials in 1 mL solutions at two different pH values (pH = 2, pH = 7) in the presence and in the absence of different sacrificial electron donors (phenol, formate, and oxalate) to test the possibility to increase, with suitable donors, the amount of peroxide produced during the photo-catalytic oxygen reduction reaction. A white LED solar simulator with intensity of 1.05 sun was used to illuminate the substrates for a total time of 12 h. Before the exposure of these films to the light, every vial was filled with O₂ at the beginning and after every single H₂O₂ assay made every 4 h. The quantification of the produced hydrogen peroxide was done spectrophotometrically via the method of horseradish peroxydase/3,3’5,5’-tetramethylbenzidine (TMB) H₂O₂ quantification by following the oxidation of TMB at 653 nm using a synergy/H microplate reader, BioTek. Aliquots of every single solution (10 μL) were afterwards added into a mixture of 30 μg mL⁻¹ TMB (Sigma-Aldrich) and 0.750 ng mL⁻¹ HRP (Sigma-Aldrich) in 0.1 M citrate–phosphate buffer pH 6.0, giving a volume of 1 mL. Quantification of the produced H₂O₂ was performed using extinction coefficient values for the TMB dimer and cross-checked with a calibration curve made by measuring solutions of known H₂O₂ (Merck). The TON was calculated with a calibration curve made by measuring the absorbance of these solution in quartz cuvettes. This gives a linear relationship between absorbance and DHI content.

**Photoelectrocatalysis**

Photoelectrochemical measurements were conducted using an H-cell configuration as shown in Fig. S2 [ESI], using a Redox.me MM PEC H-CELL. Cyclic voltammetry and chronoamperometry experiments were carried out using an Ivium technologies Vertex One potentiostat, with the eumelanin-modified FTO as the working electrode, a Pt wire as the counter electrode, and an Ag/AgCl (3 M KCl) reference electrode. The electrodes were illuminated with a white LED light source with the power of 255 mW cm⁻². In our case we compared both oxygenated and deoxygenated (O₂-bubbled, Ar-purged) conditions.
