# Stable and non-toxic ultrasmall gadolinium oxide nanoparticle colloids (coating material = polyacrylic acid) as high-performance $T_1$ magnetic resonance imaging contrast agents

Xu Miao,<sup>a</sup> Son Long Ho,<sup>a</sup> Tirusew Tegafaw,<sup>a</sup> Hyunsil Cha,<sup>b</sup> Yongmin Chang,<sup>\*b</sup> In Taek Oh,<sup>c</sup> Ahmad Mohammad Yaseen,<sup>a</sup> Shanti Marasini,<sup>a</sup> Adibehalsadat Ghazanfari,<sup>a</sup> Huan Yue,<sup>a</sup> Kwon Seok Chae<sup>c</sup> and Gang Ho Lee <sup>\*a</sup>

For use as positive ( $T_1$ ) magnetic resonance imaging contrast agents (MRI-CAs), gadolinium oxide ( $Gd_2O_3$ ) nanoparticle colloids (*i.e.* nanoparticles coated with hydrophilic ligands) should be stable, non-toxic, and ultrasmall in particle diameter for renal excretion. In addition, they should have a high longitudinal water proton relaxivity ( $r_1$ ) and  $r_2/r_1$  ratio that is close to one ( $r_2$  = transverse water proton relaxivity) for high-performance. In this study, we report ultrasmall  $Gd_2O_3$  nanoparticle colloids [coating material = polyacrylic acid,  $M_w$  =  $\sim 5100$  Da] satisfying these conditions. The particle diameter was monodisperse with an average value of  $2.0 \pm 0.1$  nm. The colloidal suspension exhibited a high  $r_1$  value of  $31.0 \pm 0.1$  s<sup>-1</sup> mM<sup>-1</sup> and  $r_2/r_1$  ratio of 1.2, where  $r_1$  was  $\sim 8$  times higher than that of commercial Gd-chelates: the cooperative induction model was proposed to explain this. The effectiveness of the colloidal suspension as a high-performance  $T_1$  MRI-CA was confirmed by taking *in vivo*  $T_1$  MR images in a mouse after intravenous administration. Highly positive contrast enhancements were observed in various organs of the mouse such as the liver, kidneys, and bladder. The colloidal suspension was then excreted through the bladder.

## Introduction

Magnetic resonance imaging contrast agents (MRI-CAs) allow us to discriminate between normal and abnormal tissues inside the body through the differential contrast enhancement between them.<sup>1–3</sup> This occurs owing to the differential population of the MRI-CAs between them. Because the proton spin relaxation times are shortened by the MRI-CAs, higher contrast MR images can be observed in regions where the MRI-CAs are more concentrated. The currently used positive ( $T_1$ ) MRI-CAs are molecular Gd-chelates and generally exhibit longitudinal water proton relaxivity ( $r_1$ ) values of 3–5 s<sup>-1</sup> mM<sup>-1</sup> ( $r_2/r_1$  = 1.1–1.2), where  $r_2$  is the transverse water proton relaxivity.<sup>4–6</sup> However, gadolinium oxide ( $Gd_2O_3$ ) nanoparticles have exhibited  $r_1$  values higher than these values.<sup>7–9</sup> Therefore, the synthesis of high-performance (or powerful)  $T_1$  MRI-CAs using

$Gd_2O_3$  nanoparticles<sup>7–9</sup> including various Gd-containing polymeric<sup>5</sup> and nanosystems<sup>10–13</sup> is currently a hot topic.

To be applied as  $T_1$  MRI-CAs,  $Gd_2O_3$  nanoparticle colloids (*i.e.* nanoparticles coated with hydrophilic ligands) should be stable, non-toxic, and ultrasmall in particle diameter for renal excretion. In addition, they should have a high  $r_1$  value and  $r_2/r_1$  ratio that is close to one for high-performance. For colloidal stability and biocompatibility,  $Gd_2O_3$  nanoparticles should be coated with hydrophilic and biocompatible ligands. Here, a more hydrophilic ligand is preferred for surface-coating because it can afford a higher colloidal stability and, importantly, a higher  $r_1$  value as well,<sup>14–16</sup> because it can allow more water molecules to access the nanoparticle. Renal excretion of  $Gd_2O_3$  nanoparticle colloids is essential for *in vivo* applications because the  $Gd^{3+}$  ion is toxic.  $Gd^{3+}$  ions can cause nephrogenic systemic fibrosis (NSF) when released inside the body.<sup>17–19</sup> Therefore, the particle diameter should be less than 3 nm for renal excretion.<sup>20–22</sup> In a previous study,  $r_1$  was optimal at a particle diameter of  $\sim 2$  nm.<sup>23</sup> This implies that high performance  $T_1$  MRI-CAs can be synthesized using ultrasmall  $Gd_2O_3$  nanoparticle colloids with a particle diameter of  $\sim 2$  nm, as thus investigated in this study. In addition this study as a continuation of the previous study<sup>23</sup> employed polyacrylic acid (PAA) as surface-coating ligand to obtain stable nanoparticle colloids and as a result to achieve high-performance *in vivo*  $T_1$  MRI.

Several Gd-nanosystems with very high  $r_1$  values have been reported.<sup>14,24–26</sup> Ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoplates with a diameter of 2 nm coated with PAA–octylamine (OA) showed an  $r_1$  value of 47.2 s<sup>−1</sup> mM<sup>−1</sup> ( $r_2/r_1 = 1.7$ ) at 1.41 T.<sup>14</sup> Dense Gd<sup>3+</sup> ions conjugated on the surface of carbon nanotubes (CNTs) exhibited an  $r_1$  value of 70 s<sup>−1</sup> mM<sup>−1</sup> ( $r_2/r_1 = 1.5$ ) at 1.41 T and 37 °C (ref. 24) and those prepared inside CNTs showed an  $r_1$  value of 94 s<sup>−1</sup> mM<sup>−1</sup> at 1.41 T and 37 °C.<sup>25</sup> Gd<sup>3+</sup>-ion clusters within ultra-short single-walled CNTs exhibited an  $r_1$  value of 164 s<sup>−1</sup> mM<sup>−1</sup> in an 1% sodium dodecyl benzene sulfate aqueous solution and 173 s<sup>−1</sup> mM<sup>−1</sup> in a pluronic F98 surfactant aqueous solution at 1.41 T and 40 °C.<sup>26</sup> These  $r_1$  values are significantly higher than those of Gd-chelates.<sup>4–6</sup> To understand these high  $r_1$  values including that observed in this study, a cooperative induction model was proposed. In this model, several Gd<sup>3+</sup> ions exposed on the nanoparticle surface or in the Gd<sup>3+</sup> ion cluster cooperatively induce the longitudinal water proton relaxation of a water molecule. Using this model, we gave a successful explanation for these high  $r_1$  values. It is worth noting that for *in vivo* applications, spherical nanoparticles are preferred over other shapes and complex systems because of their better transport through capillary vessels. In this respect, the ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloid is one of the potential high-performance  $T_1$  MRI-CAs.

In this study, we report the facile one-pot synthesis and *in vitro* and *in vivo* characterization of ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloids (core  $d_{\text{avg}} = 2.0$  nm; coating material = PAA,  $M_w = \sim 5100$  Da). PAA is a well-known biocompatible and hydrophilic polymer,<sup>27</sup> possessing one carboxyl group per monomer unit (as a result, numerous carboxyl groups per polymer) (Fig. 1). PAA binds to the nanoparticle surface through electrostatic bonding between its carboxyl groups and Gd<sup>3+</sup> ions exposed on the nanoparticle surface. Multiple binding of PAA through its many carboxyl groups with a nanoparticle allows strong binding with the nanoparticle, leading to excellent colloidal stability and

biocompatibility. To demonstrate that ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloids can be used as a high-performance  $T_1$  MRI-CA, we measured the cellular toxicity, water proton relaxivities, and *in vivo*  $T_1$  MR images after intravenous administration. In addition, the cooperative induction model was employed to explain the observed high  $r_1$  value.

## Experimental

### Chemicals

All chemicals including GdCl<sub>3</sub>·xH<sub>2</sub>O (99.9%), NaOH (>99.9%), triethylene glycol (TEG) (99%), and PAA ( $M_w = \sim 5100$  Da) were purchased from Sigma-Aldrich and used as received. Ethanol (99%, Duksan, South Korea) was used for initial nanoparticle washing. Triple distilled water was used for final nanoparticle washing and the preparation of an aqueous colloidal suspension.

### Synthesis of ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloids

The one-pot synthesis of ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloids (coating material = PAA) is shown in Fig. 1. Three solutions were prepared: (1) a precursor solution made of 1 mmol of GdCl<sub>3</sub>·xH<sub>2</sub>O and 10 mL of TEG in a 100 mL three-neck-flask, (2) a solution made of 4 mmol of NaOH and 10 mL of TEG in a 100 mL beaker, and (3) 0.05 mmol of PAA in a mixture of 5 mL of TEG and 5 mL of triple distilled water in a 100 mL beaker. Solution (1) was magnetically stirred at room temperature under atmospheric conditions until the precursor was dissolved in TEG. Solution (2) was slowly added to the precursor solution until the pH of the solution reached  $\sim 10$ . The resulting mixture solution was gradually heated to 110 °C and magnetically stirred for 4 h. The reaction temperature decreased to 80 °C. Solution (3) was slowly added to the reaction solution, and then the reaction solution was magnetically stirred for 24 h at that temperature. The product solution was cooled to room temperature and transferred to a 500 mL beaker. Then, 400 mL

Fig. 1 Reaction scheme for the one-pot synthesis of ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloid and PAA structure.

of ethanol was added to the product solution, which was magnetically stirred for 10 min. The product nanoparticle colloids were allowed to settle to the bottom of the beaker for a week in a refrigerator (4 °C). The transparent supernatant was decanted to remove unreacted precursors, free PAA, and TEG. This washing process with ethanol was repeated three times. To remove ethanol, the product solution was diluted with 400 mL of triple distilled water and then concentrated using a rotary evaporator. This process was repeated three times. The obtained concentrated colloidal suspension was split into two equal parts: one part was diluted with triple distilled water to prepare a colloidal suspension (~30 mM Gd), and the other part was dried in air to obtain a powder sample for various characterizations.

### General characterizations of ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloids

The particle diameter ( $d$ ) of the colloidal suspension was measured using a high-resolution transmission electron microscope (HRTEM) (Titan G2 ChemiSTEM CS Probe, FEI) operated at 200 kV. A drop of the sample solution diluted in ethanol was placed on a carbon film supported by a 200-mesh copper grid using a micropipette (Eppendorf, 2–20  $\mu$ L) and allowed to dry in air at room temperature. The copper grid with nanoparticle colloids was subsequently placed inside the HRTEM vacuum chamber for measurement.

The Gd-concentration of the colloidal suspension was determined using an inductively coupled plasma atomic emission spectrometer (ICPAES) (IRIS/AP, Thermo Jarrell Ash Co.). All samples were pre-treated with acids to completely dissolve the nanoparticle colloids in solution before measurement.

A dynamic light scattering (DLS) particle size analyzer (UPA-150, Microtrac) was used to measure the hydrodynamic diameter ( $a$ ) of the nanoparticle colloids using a sample solution (~0.01 mM Gd).

The colloidal stability was investigated by measuring the backscattering (BST) of near infrared (NIR) beam (880 nm) as a function of height ( $h$ ) ( $h = 5$  to 10 mm from the vial bottom containing the sample solution) and time ( $t$ ) for  $t = 0$  to 3 days using a Turbiscan (Turbiscan AGS, Formulaction).

A multi-purpose X-ray diffractometer (X'PERT PRO MRD, Philips) with unfiltered CuK $\alpha$  radiation ( $\lambda = 0.154184$  nm) was used to characterize the crystal structures of the powder samples. A scan step of  $2\theta = 0.03^\circ$  and a scan range of  $2\theta = 15$ – $100^\circ$  were used.

The attachment of PAA to ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticles was probed by recording the Fourier transform infrared (FT-IR) absorption spectra using an FT-IR absorption spectrometer (Galaxy 7020A, Mattson Instruments, Inc.) and employing powder samples pelletized with KBr. The scan range was 400–4000  $\text{cm}^{-1}$ .

A thermogravimetric analysis (TGA) instrument (SDT-Q600, TA Instruments) was used to estimate the surface-coating amount by recording the TGA curve between room temperature and 900 °C under an air flow. An average amount of surface-coated PAA was estimated from the mass loss, after

taking into account the water and air desorption between room temperature and ~105 °C. The amount of Gd<sub>2</sub>O<sub>3</sub> was estimated from the remaining mass. It was also estimated by measuring the Gd weight percent of a powder sample using an ICPAES. After TGA, the remaining sample was collected and subjected to X-ray diffraction (XRD) analysis.

### Relaxivity and map image measurements

The longitudinal ( $T_1$ ) and transverse ( $T_2$ ) relaxation times and the longitudinal ( $R_1$ ) and transverse ( $R_2$ ) map images were measured using a 1.5 T MRI scanner (GE 1.5 T Signa Advantage, GE Medical Systems) equipped with a knee coil (EXTREM). Aqueous dilute solutions (0.1, 0.05, 0.025, 0.0125, and 0.00625 mM Gd) were prepared *via* dilution of the concentrated colloidal suspension with triple distilled water. These dilute solutions and triple distilled water were then used to measure the  $T_1$  and  $T_2$  relaxation times and  $R_1$  and  $R_2$  map images. Subsequently, the  $r_1$  and  $r_2$  values of the colloidal suspension were estimated from the slopes of the plots of  $1/T_1$  and  $1/T_2$ , respectively, *versus* the Gd concentration.  $T_1$  relaxation time measurements were performed using an inversion recovery method. In this method, the inversion time (TI) was varied at 1.5 T, and the MR images were acquired at 35 different TI values in the range from 50 to 1750 ms. The  $T_1$  relaxation times were then obtained from the nonlinear least-squares fits to the measured signal intensities at various TI values. For the measurements of  $T_2$  relaxation time, the Carr–Purcell–Meiboom–Gill pulse sequence was used for multiple spin-echo measurements. Then, 34 images were acquired at 34 different echo time (TE) values in the range from 10 to 1900 ms. The  $T_2$  relaxation times were obtained from the nonlinear least-squares fits to the mean pixel values for the multiple spin-echo measurements at various TE values. The parameters used for the measurements were as follows: external MR field ( $H$ ) = 1.5 T; temperature ( $T$ ) = 22 °C; number of acquisitions (NEX) = 1; field of view (FOV) = 16 cm; FOV phase = 0.5; matrix size = 256  $\times$  128; slice thickness = 5 mm; pixel spacing = 0.625 mm; pixel band width = 122.10 Hz; and repetition time (TR) = 2000 ms.

### In vitro cytotoxicity measurements

The biocompatibility of the colloidal suspension was determined using a CellTiter-Glo luminescent cell viability assay (Promega), where intracellular adenosine triphosphate (ATP) was quantified using a luminometer (Victor 3, Perkin-Elmer). Human prostate cancer (DU145) and normal mouse hepatocyte (NCTC1469) cell lines (both cell lines were purchased from American Type Culture Collection, Rockville, MD, USA) were seeded on a 24-well cell culture plate and incubated for 24 h (5 vol% CO<sub>2</sub>, 37 °C). Five test solutions (1.6, 7.9, 15.7, 31.4, and 78.6  $\mu$ g Gd per mL) were prepared *via* dilution of the concentrated colloidal suspension with a sterile phosphate-buffered saline solution, and ~2  $\mu$ L aliquots were used to treat the cells, which were subsequently incubated for 48 h. The viability of the treated cells was measured and normalized with respect to that of untreated control cells. Each measurement was performed in duplicate to obtain the average cell viabilities.

## Animal experiment

This study was performed in accordance with the Korean guidelines and approved by the animal research committee of Kyungpook National University.

### *In vivo* $T_1$ MR image measurements in the mouse

One SD (Sprague Dawley®) mouse was used for *in vivo* test. *In vivo*  $T_1$  MR images were acquired using the same MRI scanner that was used for the water proton relaxation time measurements. For imaging, the mouse (~120 g) was anesthetized using 1.5% isoflurane in oxygen. Measurements were performed before and after injection of the colloidal suspension into the mouse tail vein. The injection dose was typically ~0.05 mmol Gd per kg. After the measurement, the mouse was revived from the anesthesia and placed in a cage with free access to food and water. During the measurement, the temperature of the mouse was maintained at ~37 °C using a warm water blanket. The parameters used for the measurements were as follows:  $H = 1.5$  T;  $T = 37$  °C; NEX = 4; FOV = 9 mm; phase FOV = 0.5; matrix size =  $256 \times 192$ ; slice thickness = 1 mm; spacing gap = 0.5 mm; pixel bandwidth = 15.63 Hz; TR = 500 ms; and TE = 13 ms.

## Results and discussion

### Particle diameter, hydrodynamic diameter, and crystal structure

Fig. 2a presents HRTEM images, showing a monodisperse particle size distribution. The average particle diameter ( $d_{\text{avg}}$ ) was estimated to be  $2.0 \pm 0.1$  nm from a log-normal function fit to the observed particle diameter distribution (Fig. 2b and Table 1). The average nanoparticle hydrodynamic diameter ( $a_{\text{avg}}$ ) was estimated to be  $6.3 \pm 0.1$  nm from a log-normal function fit to the observed hydrodynamic diameter distribution (Fig. 2c and Table 1). The colloidal stability was investigated by measuring the BST of NIR beam as a function of  $t$  for 3 days. The  $\Delta\text{BST}(t)$  corresponding to average BST ( $t$ ) minus average BST (0) in which the average BST ( $t$ ) is the average of backscattered NIR beams for all  $h$  ( $h = 5\text{--}10$  mm) at a scan time  $t$ , exhibited negligible deviations from zero (Fig. 2d), confirming the stable colloidal suspensions at solution pH = 4–9. Note that the  $\Delta\text{BST}(t)$  is zero for ideal colloids. A sample solution photo is provided in Fig. 2e. The colloidal suspension was transparent and did not settle at the bottom of the vial for at least six months, indicating excellent colloidal stability. The Tyndall effect supported the presence of colloids (Fig. 2f): the right vial containing a sample solution exhibited light scattering due to the colloidal suspension, whereas the left vial containing triple distilled water did not.

The XRD pattern of the as-prepared powder sample was broad and amorphous (the bottom XRD pattern in Fig. 3) owing to the ultrasmall particle size. However, after TGA, the sample exhibited the cubic structure of bulk  $\text{Gd}_2\text{O}_3$  (the top XRD pattern in Fig. 3), which is attributed to crystal growth during exposure to temperatures up to 900 °C, as previously observed.<sup>28</sup> The estimated lattice constant of the TGA-treated powder

sample was 10.815 Å, which agrees with the reported value of 10.813 Å.<sup>29</sup>

### Surface-coating results

The PAA-coating on the nanoparticle surface was investigated by recording the FT-IR absorption spectrum. The FT-IR absorption spectrum of free PAA was also recorded for comparison (the top FT-IR absorption spectrum in Fig. 4a). The sample featured characteristic PAA vibrations at  $2930\text{ cm}^{-1}$  (C–H stretching),  $1550\text{ cm}^{-1}$  ( $\text{COO}^-$  antisymmetric stretching), and  $1400\text{ cm}^{-1}$  ( $\text{COO}^-$  symmetric stretching) (the bottom FT-IR absorption spectrum in Fig. 4a). PAA binds to the nanoparticle through electrostatic bonding between the  $\text{COO}^-$  groups of PAA and  $\text{Gd}^{3+}$  ions exposed on the nanoparticle surface. This bonding corresponds to hard acid ( $\text{COO}^-$  group of PAA) – hard base ( $\text{Gd}^{3+}$  ion exposed on the nanoparticle surface) type of bonding.<sup>30–32</sup> Because each PAA ( $M_w = \sim 5100$  Da) has ~54 monomer units and each monomer has a  $\text{COO}^-$  group (Fig. 1), multiple bonding between many  $\text{COO}^-$  groups of PAA and the nanoparticle is possible, forming a stable nanoparticle colloid. According to this, the surface-coating structure of PAA on the ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle surface is drawn in Fig. 4b. As estimated from TGA data (Fig. 5), approximately 13 PAA polymers were coated on each nanoparticle surface. Among approximately 54  $\text{COO}^-$  groups per PAA, part of them are conjugated to  $\text{Gd}^{3+}$  ions exposed on the nanoparticle surface and the remaining ones are free.

The amount ( $P$ ) of surface-coated PAA in weight percent was estimated to be  $53.7 \pm 0.5\%$  by measuring the mass loss in a TGA curve, after considering the water and air desorption ( $18.4 \pm 0.5\%$ ) between room temperature and ~105 °C (Fig. 5 and Table 1). The remaining mass was due to  $\text{Gd}_2\text{O}_3$  ( $27.9 \pm 0.5\%$ ), which was consistent with 31.0% estimated using the Gd weight percent of 26.9 obtained from ICPAES analysis of the powder sample. The grafting density ( $\sigma$ ), which corresponds to the average number of PAA coated per nanoparticle unit surface area,<sup>33</sup> was estimated to be  $1.0 \pm 0.1\text{ nm}^{-2}$  using the bulk density of  $\text{Gd}_2\text{O}_3$  ( $7.41\text{ g cm}^{-3}$ ),<sup>34</sup> the aforementioned estimated value of  $P$ , and the average particle diameter determined *via* HRTEM imaging. By multiplying  $\sigma$  by the nanoparticle surface area ( $\pi d_{\text{avg}}^2$ ), the average number ( $N_{\text{NP}}$ ) of PAA coated per nanoparticle was estimated to be  $13 \pm 1$  (Table 1). This large value indicates that each ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle was sufficiently coated with PAA. This explains the excellent colloidal stability and biocompatibility that were observed in this study.

### Water proton relaxivities and map images

To estimate  $r_1$  and  $r_2$  values, inverse water proton relaxation times ( $1/T_1$  and  $1/T_2$ ) were plotted as a function of the Gd concentration (Fig. 6a). The  $r_1$  and  $r_2$  values were estimated to be  $31.0 \pm 0.1$  and  $37.4 \pm 0.1\text{ s}^{-1}\text{ mM}^{-1}$  ( $r_2/r_1 = 1.2$ ), respectively, from the corresponding slopes (Table 1). This high  $r_1$  value and  $r_2/r_1$  ratio close to one, suggest that the synthesized ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle colloids are suitable for high-performance  $T_1$  MRI-CA. This is confirmed *in vitro* by their  $R_1$  and  $R_2$  map

Fig. 2 (a) HRTEM images at different magnifications [arrows in (a-III) indicate ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle colloids], (b) a log normal function fit to the observed diameter distribution, (c) a log normal function fit to the observed hydrodynamic diameter distribution, (d) plots of  $\Delta\text{BST}$  as a function of time, (e) an aqueous sample solution photo showing transparency and excellent colloidal stability, and (f) the Tyndall effect showing light scattering caused by colloids: the left vial contains triple distilled water and the right vial contains a sample solution (a commercial laser point was used as a light source).

images, which show clear dose-dependent contrast enhancements (Fig. 6b).

The  $r_1$  value of the ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle colloid was compared with those of other Gd-nanosystems (Table 2). First of all, it was  $\sim 8$  times higher than those<sup>4–6</sup> of commercial Gd-

chelates. It was also higher than those of  $\text{Gd}_2\text{O}_3$  nanoparticles with larger particle diameters,<sup>15,35,36</sup> primarily owing to its higher surface-to-volume ratio. For the similar particle size, the nanoplate<sup>14</sup> exhibited an  $r_1$  value of  $47.2 \text{ s}^{-1} \text{ mM}^{-1}$  which is higher than that of the ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle colloid.

Fig. 5 TGA curve showing the PAA surface-coating amount (53.7%) in weight percent. The weight percents of water and air (18.4%) and  $\text{Gd}_2\text{O}_3$  (27.9%) are also provided.

This is likely because the surface area of the nanoplate is larger than that of the spherical nanoparticle. Our previous study indicated that the optimal particle diameter of  $\text{Gd}_2\text{O}_3$  nanoparticles for an optimal  $r_1$  value is approximately 2 nm.<sup>23</sup> A similar particle diameter dependence of the  $r_1$  value was observed in gadolinium oxide nanoplates,<sup>14</sup> hybrid gadolinium oxide nanoparticles,<sup>20</sup> and ultrasmall  $\text{NaGdF}_4$  nanoparticles.<sup>37</sup> This implies that the most suitable particle diameter of  $\text{Gd}_2\text{O}_3$  nanoparticles for high-performance  $T_1$  MRI-CAs is approximately 2 nm, which was used in this study.

#### Cooperative induction model for the observed high $r_1$ value

Theory of water proton relaxation is very complex.<sup>4,5,38</sup> To understand high  $r_1$  values observed in this study and in various

Gd-nanosystems,<sup>14,24–26</sup> however, a simple cooperative induction model was empirically proposed here. In this model, several  $\text{Gd}^{3+}$  ions on the nanoparticle surface or in the dense  $\text{Gd}^{3+}$  ion cluster cooperatively induce the longitudinal water proton relaxation of a water molecule. Therefore, the  $r_1$  value increases with increasing the number ( $N$ ) of the  $\text{Gd}^{3+}$  ions interacting with a water molecule because a water molecule experiences stronger induction of its longitudinal water proton relaxation if many  $\text{Gd}^{3+}$  ions cooperatively induce its longitudinal water proton relaxation than by a single  $\text{Gd}^{3+}$  ion. In addition the  $r_1$  value increases with increasing the coordination number ( $q$ ) of the  $\text{Gd}^{3+}$  ion with water molecules. Therefore, as the sum of the values ( $N + q$ ) increases, the  $r_1$  value increases. However, the  $N$  (*i.e.* the cooperative induction) effect on  $r_1$  is more significant than the  $q$  effect as described below. To illustrate this and the cooperative induction, four Gd-systems are depicted in Fig. 7. Both the Gd-chelate and free  $\text{Gd}^{3+}$  ion have no cooperative

Fig. 4 (a) FT-IR absorption spectra of a powder sample and free PAA ( $M_w = \sim 5100$  Da): 3325  $\text{cm}^{-1}$  (O–H stretch from water); 2930  $\text{cm}^{-1}$  (C–H stretch from PAA); 1660  $\text{cm}^{-1}$  (O–H bend from water); 1550  $\text{cm}^{-1}$  ( $\text{COO}^-$  antisymmetric stretch from PAA); and 1400  $\text{cm}^{-1}$  ( $\text{COO}^-$  symmetric stretch from PAA). (b) Surface-coating structure of PAA on the ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle surface.

Table 2  $r_1$  and  $r_2/r_1$  values for various  $\text{Gd}_2\text{O}_3$  nanosystems, a free  $\text{Gd}^{3+}$  ion, and  $\text{Gd-DTPA}^a$ 

Chemical	Particle diameter (nm)	Ligand	Temperature ( $^{\circ}\text{C}$ )	Applied field ( $T$ )	$r_1$ ( $\text{s}^{-1} \text{mM}^{-1}$ )	$r_2/r_1$	Ref.
$\text{Gd}^{3+}$	—	DTPA	19.5	1.5	4.1	1.1	6
Free $\text{Gd}^{3+}$	—	—	19.5	1.5	10.5	1.2	6
$\text{Gd}_2\text{O}_3$ nanoplate	2	Oleic acid	—	1.41	8.0	3.3	14
$\text{Gd}_2\text{O}_3$ nanoplate	2	PAA-OA	—	1.41	47.2	1.7	14
$\text{Gd}_2\text{O}_3$ nanoparticle	3–5	Mal-PEG-NHS-MPTS	22	1.5	22.8	1.4	15
$\text{Gd}_2\text{O}_3$ nanoparticle	20–40	Dextran	37	7.05	4.8	3.5	35
$\text{Gd}_2\text{O}_3$ nanoparticle	2.0	PAA	22	1.5	31.0	1.2	This work

<sup>a</sup> DTPA: diethylenetriaminepentaacetic acid. Mal-PEG-NHS-MPTS:  $\alpha$ -maleinimido- $\omega$ -carboxysuccinimidyl ester poly(ethylene glycol)-(3-mercaptopropyl)tri-methoxysilane. PAA-OA: polyacrylic acid-octylamine.

induction effect because their  $N$  equals 1. Therefore, as given in Table 2, the higher  $r_1$  value of the free  $\text{Gd}^{3+}$  ion ( $1 \leq q \leq 9$ ) compared with the  $\text{Gd}$ -chelate ( $q = 1$ ) is owing to its higher  $q$  value. This study revealed that  $r_1$  value of the ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle ( $1 \leq q \leq 6$  for a cubic  $\text{Gd}_2\text{O}_3$ ,  $N > 1$ ) was  $\sim 3$  times higher than that of the free  $\text{Gd}^{3+}$  ion even though the latter has a higher  $q$  value. Therefore, the higher  $r_1$  value of the former is due to its higher  $N$  value compared with the latter. This indicates that the  $N$  should play a more significant role in  $r_1$  value than the  $q$  does. Both  $N$  and  $q$  values of the dense  $\text{Gd}^{3+}$  ion cluster are higher than the respective values of the ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle:  $q$  of the  $\text{Gd}^{3+}$  ion in the dense  $\text{Gd}^{3+}$  ion cluster is similar to that of the free  $\text{Gd}^{3+}$  ion and thus higher than that of the nanoparticle, and  $N$  of the  $\text{Gd}^{3+}$  ion cluster is also higher than that of the nanoparticle because all the  $\text{Gd}^{3+}$  ions in the  $\text{Gd}^{3+}$  ion clusters can contribute to inducing the longitudinal water proton relaxation whereas in nanoparticles, only the  $\text{Gd}^{3+}$  ions exposed on the nanoparticle surface dominantly contribute to the induction. This explains  $r_1$  values of 70–173  $\text{s}^{-1} \text{mM}^{-1}$  of the dense  $\text{Gd}^{3+}$  ion clusters prepared inside and outside CNTs,<sup>24–26</sup> which were 2 to 6 times higher than that

of the ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle in this study. In this way, all the experimental observations of  $r_1$  ( $\text{Gd}^{3+}$  ion cluster)  $> r_1$  (ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle)  $> r_1$  (free  $\text{Gd}^{3+}$ )  $> r_1$  ( $\text{Gd}^{3+}$ -chelate) can be explained using this simple model. Therefore, the cooperative induction effect plays an important role in  $r_1$  value and thus should be considered in designing high-performance  $T_1$  MRI-CAs with high  $r_1$  values.

### Cytotoxicity results

The biocompatibility of the colloidal suspension was demonstrated *in vitro* by measuring cellular cytotoxicities using DU145 and NCTC1469 cell lines. As shown in Fig. 8, the colloidal suspension was non-toxic up to 78.6  $\mu\text{g}$   $\text{Gd}$  per mL and thus, suitable for *in vivo* applications. Recently, accumulation of  $\text{Gd}$  in the brain has been a big issue due to possible neurotoxicity. Therefore, a further study to evaluate the  $\text{Gd}$  deposition in the brain *ex vivo* is needed, which will be carried out in a future.

### *In vivo* $T_1$ MR images

The effectiveness of the colloidal suspension as a high-performance  $T_1$  MRI contrast agent was evaluated by taking *in vivo*  $T_1$  MR images in a mouse after intravenous administration into the tail. As shown in Fig. 9a, positive contrast enhancements were observed in the liver, kidney lobes, kidney renal pelvis, ureter, and bladder and then decreased with time because of the excretion of the nanoparticle colloids through the bladder. In addition, owing to the high contrasts and

Fig. 7 Four  $\text{Gd}$ -systems showing the interaction (labelled as dotted lines) between  $\text{Gd}^{3+}$  ions and water molecules: (a)  $\text{Gd}^{3+}$ -chelate (the chelate is drawn arbitrarily), (b) free  $\text{Gd}^{3+}$  ion, (c) ultrasmall  $\text{Gd}_2\text{O}_3$  nanoparticle, and (d) dense  $\text{Gd}^{3+}$  ion cluster.

Fig. 8 *In vitro* cellular cytotoxicities of a sample solution in DU145 and NCTC1469 cell lines, showing non-toxicity up to 78.6  $\mu\text{g}$   $\text{Gd}$  per mL.

Fig. 9 (a) *In vivo* T<sub>1</sub> MR images in various organs of a mouse (circles label ROIs used for SNR plots) after intravenous administration: (I) liver (labelled as "L"), (II) kidneys ("Lo": kidney lobes, "RP": kidney renal pelvis, and "U": ureter), and (III) bladder (labelled as "B"), (b) nomenclature of the lobes, renal pelvis, and ureter in the kidneys, and (c) SNR plots of ROIs in various organs of the mouse as a function of time (pre = before and post = just after intravenous administration).

ultrasmall diameters, excretion of the nanoparticle colloids through the lobes, renal pelvis, and ureter of the kidneys (see Fig. 9b for nomenclature) was observed. To clearly show contrast changes with time, the signal-to-noise ratios (SNRs) of region of interests (ROIs) in organs (labelled as circles in Fig. 9a) were plotted as a function of time (Fig. 9c), exhibiting that the contrasts initially increased, reached the maxima, and then decreased with time in all organs. For the liver, the nanoparticle colloids showed the highest contrast enhancement around 10 min after intravenous administration and then the contrast gradually decreased with time. This contrast enhancement pattern in the liver suggests that the nanoparticle colloids were not taken up by reticuloendothelial system of the liver. The colloidal suspension was finally excreted through the bladder, which is consistent with the other ultrasmall nanoparticle systems' behavior with  $d < 3$  nm.<sup>20–22</sup>

As demonstrated, the ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloids were stable and non-toxic and excreted through the renal system owing to their ultrasmall particle diameter, proving their suitability for use as T<sub>1</sub> MRI-CA. In addition they exhibited a very high  $r_1$  value with an  $r_2/r_1$  ratio close to one, and as a result, high contrast T<sub>1</sub> MR images in the mouse. Therefore, the ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloids synthesized in this study can be used as a high-performance T<sub>1</sub> MRI-CA.

## Conclusions

We reported the facile one-pot synthesis and characterization of ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloids (coating material = PAA,  $M_w = \sim 5100$  Da) *in vitro* and *in vivo*. The results are as follows.

(1) The particle diameter was monodisperse and ultrasmall (core  $d_{\text{avg}} = 2.0 \pm 0.1$  nm).

(2) The colloidal suspension was stable and biocompatible owing to the PAA-coating on the nanoparticle surface. Cytotoxicity tests using two cell lines showed non-toxicity up to 78.6  $\mu\text{g}$  Gd per mL.

(3) The colloidal suspension exhibited  $r_1 = 31.0 \pm 0.1$  and  $r_2 = 37.4 \pm 0.1$  s<sup>-1</sup> mM<sup>-1</sup> ( $r_2/r_1 = 1.2$ ). The  $r_1$  value was  $\sim 8$  times higher than those of commercial Gd-chelates. We attribute this to the ultrasmall particle diameter and the hydrophilic PAA-coating on the nanoparticle surface. The cooperative induction model was proposed to explain this high  $r_1$  value.

(4) The colloidal suspension exhibited high contrast T<sub>1</sub> MR images in various organs of the mouse after intravenous administration and was finally excreted through the renal system. Therefore, the synthesized ultrasmall Gd<sub>2</sub>O<sub>3</sub> nanoparticle colloids should be a potential candidate for use as a high-performance T<sub>1</sub> MRI-CA.

## Author contributions

Xu Miao carried out synthesis, measurements and characterizations, Son Long Ho contributed to the synthesis, Hyunsil Cha and Yongmin Chang measured relaxivities and MR images, In Taek Oh and Kwon Seok Chae measured cellular toxicities, Tirusew Tegafaw, Ahmad Mohammad Yaseen, Shanti Marasini,

Adibehalsadat Ghazanfari and Huan Yue contributed to experiments, and Gang Ho Lee wrote the manuscript.
