Highly enhanced response of MoS_2 /porous silicon nanowire heterojunctions to NO_2 at room temperature†

Shufen Zhao, ^a Zhengcao Li, ^{*ab} Guojing Wang, ^a Jiecui Liao, ^a Shasha Lv^a and Zhenan Zhu^c

Molybdenum disulfide/porous silicon nanowire ($\text{MoS}_2/\text{PSiNW}$) heterojunctions with different thicknesses as highly-responsive NO_2 gas sensors were obtained in the present study. Porous silicon nanowires were fabricated using metal-assisted chemical etching, and seeded with different thicknesses. After that, MoS_2 nanosheets were synthesized by sulfurization of direct-current (DC)-magnetic-sputtering Mo films on PSiNWs. Compared with the as-prepared PSiNWs and MoS_2 , the $\text{MoS}_2/\text{PSiNW}$ heterojunctions exhibited superior gas sensing properties with a low detection concentration of 1 ppm and a high response enhancement factor of ~ 2.3 at room temperature. The enhancement of the gas sensitivity was attributed to the layered nanostructure, which induces more active sites for the absorption of NO_2 , and modulation of the depletion layer width at the interface. Further, the effects of the deposition temperature in the chemical vapor deposition (CVD) process on the gas sensing properties were also discussed, and might be connected to the nucleation and growth of MoS_2 nanosheets. Our results indicate that $\text{MoS}_2/\text{PSiNW}$ heterojunctions might be a good candidate for constructing high-performance NO_2 sensors for various applications.

1. Introduction

Gas sensors play an important role in monitoring the environment and detecting air pollution. Many factors affect the gas sensing capacity of a gas sensor, including the materials, sensing mechanism and environmental effects (temperature, humidity).^{1,2} Recently, many researchers have devoted their efforts to developing sensors with high sensitivity and low operating temperatures.³ It is well known that semiconducting materials are used in gas sensors, such as metal oxides, silicon, and two-dimensional (2D) materials. Metal oxides are a common material to be employed for gas detection.^{4–6} However, they exhibit poor conductivity and require high temperatures to operate.⁷ In particular, silicon and two-dimensional (2D) materials have been widely used in low-temperature sensors.^{8,9}

Silicon has many advantages including stability, abundance and optical properties, and it can be employed in

microelectronic technologies.¹⁰ Among these silicon-based materials, PSiNW materials are one of the most promising n-type semiconductors, as they possess large surface areas and high chemical reactivity.¹¹ For these reasons, they are widely used in gas sensing devices. PSiNWs are impressive as they can be easily integrated with other semiconductors to lower the operating temperature of the resulting gas sensor.¹² However, there are several disadvantages, such as poor sensitivity and oxidation of the surface of the material at room temperature.

2D materials such as graphene and MoS_2 are developing rapidly, with high surface-to-volume ratios.¹³ MoS_2 has a 2D layered structure and its band gap is affected by the number of stacked layers.¹⁴ Monolayer MoS_2 is an n-type semiconductor with a direct band gap of ~ 1.9 eV, while bilayer and thicker MoS_2 crystals have indirect band gaps of ~ 1.3 eV.^{15,16} MoS_2 is used as a gas sensor mainly because of its various sites (sulfur defects, vacancies, and edge sites).¹⁷ Thermal treatments can improve device performance.¹⁸ Moreover, compared with other synthetic methods, CVD has the obvious advantages of thickness control^{19,20} and the ability for large-scale growth of MoS_2 .²¹

MoS_2 could act as a protecting layer for PSiNWs against oxidation damage when applied to gas sensor devices. However, few studies have reported application of $\text{MoS}_2/\text{PSiNW}$ heterojunctions to gas sensing. In this paper, $\text{MoS}_2/\text{PSiNW}$ heterojunctions fabricated on a substrate with Ag electrodes are presented. The effects of the thickness and deposition temperatures on the gas sensing properties were also explored.

As a consequence, $\text{MoS}_2/\text{PSiNW}$ heterojunctions with different morphologies showed high sensitivity, low operating temperatures and fast response/recovery properties. This study represents an important step to improve gas sensing properties through the synthesis of $\text{MoS}_2/\text{PSiNW}$ heterojunctions.

2. Experimental section

2.1. Sensor fabrication process

$\text{MoS}_2/\text{PSiNW}$ heterojunctions were fabricated on $\langle 100 \rangle$ orientation, n-type Si substrates using Ag-assisted chemical etching, direct current (DC) magnetic sputtering and chemical vapor deposition (CVD) methods, as shown in Fig. 1. The fabrication process is further explained as follows. The silicon wafers were cut and ultrasonically cleaned in acetone, ethanol and deionized water for 15 min each. Then they were immersed in boiling $\text{H}_2\text{SO}_4/\text{H}_2\text{O}_2$ solution at 135°C for 1 h to remove the organic contaminants. To remove the silicon oxide layer, they were treated with 5% HF before use. PSiNWs were synthesized using a metal-assisted chemical etching method. Pre-treated silicon wafers were placed into a mixed solution of 4.8 M HF and 5 mM AgNO_3 to obtain a layer of Ag nanoparticles, and were then immersed into a solution of 4.8 M HF and 0.3 M H_2O_2 at 30°C . Ag nanoparticles on the silicon substrate play an important role as catalysts in the etching process. An etching time of 15 min was selected, and we obtained PSiNWs after the etching process was finished. To remove residual Ag nanoparticles and the silicon oxide layer, the PSiNWs were dipped in HNO_3 solution and HF solution successively. After each procedure, they were washed with plenty of water.

Mo atoms were deposited onto the PSiNW substrate using direct current (DC) magnetic sputtering, which could control different thicknesses. The deposition was carried out with 70 W power and a working Ar pressure of 0.3 Pa, and the base pressure was below 10^{-4} Pa. We selected three parameters of the magnetic sputtering time for the Mo seed layers (1 min, 3 min and 5 min), used to control the thickness of the Mo seed layer on the PSiNW substrate.

MoS_2 nanosheets were grown on PSiNWs using chemical vapor deposition (CVD). After the deposition of seed layers on the PSiNW substrates, the substrates were placed at the center of the furnace and sulfur powder (1.5 g) was placed at the upstream end. Two temperature ranges were used to separate the PSiNW substrates covered by Mo seed layers and sulfur powder. Sulfur powder (1.5 g) was placed upstream of the quartz tube at a distance of 10 cm from annealing furnace. At the beginning, a PSiNW substrate covered by Mo seed layers was put on a quartz boat, which was still downstream of quartz and outside of the annealing furnace. The annealing furnace needed to be checked for air tightness and N_2 was injected to get rid of residual air. The temperature of the center zone was increased to 770°C at a ramp rate of 14°C for the growth process and the upstream zone was heated to 130°C at a ramp rate of 26°C for vaporization of elemental sulfur powders. After the center zone had risen to 770°C and the upstream zone had been maintained at 130°C , the quartz boat was pushed into the center of the furnace with a magnet and maintained for 90 min. Finally, the samples were moved out of the furnace after natural cooling. During whole process, the flow rate of Ar carrier gas was maintained at 200 standard cubic centimeters per minute (SCCM). We marked samples as “ $\text{MoS}_2/\text{PSiNWs-1 min}$ ”, “ $\text{MoS}_2/\text{PSiNWs-3 min}$ ” and “ $\text{MoS}_2/\text{PSiNWs-5 min}$ ”, according to the magnetic sputtering time (1 min, 3 min and 5 min, respectively) of the Mo seed layers. To study the effect of deposition temperature in the chemical vapor deposition process on the gas sensing behaviors, three distinct $\text{MoS}_2/\text{PSiNW}$ heterojunctions with different deposition temperatures of 720°C , 770°C and 820°C were synthesized, named “S-1”, “S-2” and “S-3”, respectively.

2.2. Characterization

The surface morphologies and microstructures were characterized using scanning electron microscopy (SEM, JEOL-JSM 7001F, Tokyo, Japan) and high-resolution transmission electron microscopy (HRTEM, JEM-2100F). X-ray photoelectron spectroscopy (XPS, ESCALAB250Xi, Thermo, Waltham, MA, America) used the C 1s signal (284.8 eV) as a reference to calibrate the binding energy. X-ray diffraction (XRD) patterns were obtained on a Rigaku Smart Lab (Tokyo, Japan) and Raman spectra were obtained using a Lab Ram HR Evolution Micro Raman Spectrometer. These patterns and spectra were used to analyze the structural features and phase purity of the $\text{MoS}_2/\text{PSiNW}$ heterojunctions. Raman microscopy was performed with an excitation wavelength of 532 nm.

2.3. Gas sensing measurements

To measure the gas sensing properties of the samples, two silver electrodes were deposited onto them using printing, and connected to a digital resistance measurement system. Then the experiment was carried out in a home-made system. The testing chamber used was a 250 mL metal chamber, and gas would fill the chamber in 30 seconds based on the flow rate used. Gases used for the test were NO_2 (0.01% NO_2 with 99.99% N_2) and pure N_2 (99.999%). At the beginning, pure N_2 was needed to inject

Fig. 1 Fabrication process of the $\text{MoS}_2/\text{PSiNW}$ -based sensor devices.

into the chamber. After the resistance of the samples reached a stable value, gases were mixed to obtain certain concentrations and injected into the chamber until a new constant value of the concentration was achieved. The measuring system recorded the resistance of the sensors at all times. By controlling the mass flow to change the specific gas concentration, the computer recorded the resistance change of the samples *versus* the concentration of NO₂. The gas filled the chamber within few seconds and such a setup was found to be appropriate for the gas sensing measurements. Response was one of main gas sensing properties, which is defined as follows:

$$\text{Response (\%)} = \frac{R_g - R_0}{R_0} \times 100\%$$

where R_g is the measured electric resistance of a gas sensor at a certain concentration of NO₂ and R_0 is the resistance in a pure N₂ atmosphere.

3. Results and discussion

Scanning electron microscopy (SEM) was used to characterize the morphology of the samples. Fig. 2a and c show the top view and side view of the PSiNWs obtained *via* Ag-assisted chemical etching. The surface morphology of the PSiNWs is rough and the tip parts are clustered. The obtained porous silicon nanowires are arranged vertically on the silicon substrates with good alignment. MoS₂ nanosheets grown on wafers using CVD are shown in Fig. 2b and d. The MoS₂ nanosheets are distributed on the silicon substrate uniformly. The observable MoS₂ film consists of vertically standing nanosheets. Abundant MoS₂ nanosheet layers provide large quantities of edge sites, which are beneficial for gas sensing properties.

Fig. 3 shows the thickness evolution and surface morphology of MoS₂ nanosheets grown on PSiNWs using CVD. The deposition rate of MoS₂ on the silicon wafers was \sim 20 nm min⁻¹. Fig. 3a and c show the top view and side view of edge-exposed MoS₂ nanosheets on PSiNWs. The MoS₂ nanosheets are grown densely on the top and lateral surfaces of the PSiNWs, which increases the reactive areas for gas molecules. The magnified view of the surface with obvious edges indicates the possibility of layer structure growth. An increase in the thicknesses of the MoS₂ nanosheets seems to appear near the edges, where they begin to cluster (Fig. 3b and d). Fig. 3c and d show that isolated nanosheets are clustered together to form densely layered stacked structures. One can see that quantities of MoS₂ nanosheets are interconnected with each other and generate many holes or channels for gas to quickly diffuse from the surface to the inside of the nanostructure. The distribution of MoS₂ nanosheets on the lateral surface of PSiNWs was further examined using transmission electron microscopy (TEM).

TEM was used to analyze the nanostructure and elemental distribution. Fig. 4a shows that the rod-like morphology still

Fig. 4 (a) The morphology of MoS₂/PSiNW nanostructures. (b) The high-resolution TEM image and selective area electron diffraction (SAED) pattern. (c) The site of line scanning and (d) the elemental distribution of Si, Mo and S. Details for the elements Mo (1), S (2) and Si (3).

remains after forming MoS₂ nanosheets on the PSiNW nanostructures. The MoS₂ nanosheets are uniformly distributed on the surface of a single porous silicon nanowire. Fig. 4b clearly shows that each layer consists of an edge atomic structure with the S-Mo-S sequence, because the Mo atoms are heavier and appear brighter. The thickness of the Mo seed layer can change the horizontal and vertical alignment of MoS₂.²² Many stripes are at the edges of MoS₂ nanosheets, which reveal vertically aligned 2D MoS₂ layers. Some grains are composed of a large number of self-assembled MoS₂ layers with an interlayer spacing of 0.625 nm, which is consistent with the theoretical spacing for (002) planes of the hexagonal MoS₂ nanostructures. A selective area electron diffraction (SAED) pattern (Fig. 4b inset) reveals that the MoS₂/PSiNWs have a polycrystalline structure. The elemental distributions of Si, Mo and S are summarized in Fig. 4d. The summarized curve shows only the distribution of Mo and Si atoms, because distribution curves of Mo and S are coincident, which can be confirmed in Fig. 4 (1) and (2). Where a Mo atom is present, S atom will react with it to form MoS₂. Si atoms are mainly distributed inside of the MoS₂/PSiNW nanostructures, while Mo and S are distributed on the edges and surfaces.

The structural details and phase purity of MoS₂/PSiNW crystals were studied using XRD. All of the synthesized samples were measured with diffraction peaks in the range of 5–60°, as shown in Fig. 5a. The diffraction peaks of the MoS₂ nanosheets are observed at 14.42° and 40°, which correspond to the (002) and (103) planes (JCPDS no. 37-1492). A strong peak at 33° that belongs to Si (200) was observed.

Raman spectra give many properties of the material, namely, structural features, orientation of the facets in the crystal, transition of the material, bonding details, thermal conductivity

Fig. 5 (a) X-ray diffraction (XRD) pattern of MoS₂ nanosheets grown on PSiNWs. (b) Raman spectra of MoS₂ on PSiNWs with two major peaks: E_{2g} and A_{1g} vibration modes. XPS spectra of (c) Mo 3d, (d) S 2p, (e) Si 2p and (f) O 1s in MoS₂/PSiNW samples.

and compositional detail.²³ As Fig. 5b shows, MoS₂ has two major peaks: E_{2g} and A_{1g} vibrational modes of the Mo–S bonds near 380 cm⁻¹ and 405 cm⁻¹. E_{2g} represents the in-plane vibrational mode of the Mo and S atoms and A_{1g} represents the out-of-plane vibrational mode of S atoms.²⁴ The peak position difference (*n*) between E_{2g} and A_{1g} is about 25 cm⁻¹, which is consistent with those observed for bulk MoS₂.²⁵ The result is quite sensitive to the thickness of 2-D layered material systems, and that is consistent with what has been reported.^{26,27} Another feature observed in the Raman spectra is the intensity ratio of E_{2g}/A_{1g}, the value of which is approximately 0.6. The value indicates an obvious out-of-plane vibration (A_{1g}) mode over in-plane vibration (E_{2g}), reflecting the dominantly exposed MoS₂ edge sites. The result proves it is typical vertical growth,^{28,29} which is consistent with the TEM result shown in Fig. 4b.

The surface composition and chemical states of the MoS₂/PSiNW nanostructure were measured using X-ray photoelectron spectroscopy (XPS).²⁸ Fig. 5c exhibits the Mo 3d spectrum of the MoS₂/PSiNW nanostructure. Two peaks at 229.65 and 232.75 eV are attributed to Mo 3d_{5/2} and Mo 3d_{3/2} of Mo⁴⁺.³⁰ The other peak at 226.85 eV is in agreement with S²⁻ 2s.³¹ The S 2p spectrum in Fig. 5d shows two double peaks at 162.5 and 163.7 eV, which are ascribed to S 2p_{3/2} and S 2p_{1/2} of S²⁻, respectively.³² The binding energy is also consistent with previous reports (2p_{3/2}: 162.4 eV and 2p_{1/2}: 163.3–164.14 eV).^{33–35} Fig. 5e shows that Si has two valence states. The binding energy

of Si (2p_{3/2}) observed at 99.95 eV indicates the existence of Si–Si. Fig. 5f shows the O 1s spectrum, indicating a peak at 533.05 eV corresponding to silicon oxide.

4. Gas studies

4.1. Gas-sensing properties

Fig. 6 shows the response and recovery curves of the MoS₂/PSiNW heterojunctions with different thicknesses and substrates at room temperature. The sensitivity was measured upon sequential NO₂ exposures in the range of 1–50 ppm. The time-dependent gas sensing behaviors toward different concentrations of NO₂ are shown in Fig. 6a. MoS₂/PSiNWs-3 min exhibited the most sensitivity to NO₂, in comparison to MoS₂/PSiNWs-1 min and MoS₂/PSiNWs-5 min. The highest limit of detection was at 1 ppm. The recovery (60 min after exposure to NO₂) could not be fully completed in cycles of 50–1 ppm. The phenomenon was also observed in a graphene-based sensor³⁶ and in previous sensor reports.³⁷ Fig. 6b shows the sensing response as a function of gas concentration. The highest response values (MoS₂/PSiNWs-3 min) of each cycle were 0.27, 5.72, 10.55, 17.8 and 28.4% with NO₂ concentrations of 1, 5, 10, 20, 50 ppm. This study revealed the influence of the thickness of MoS₂ on the gas sensing properties of MoS₂/PSiNW heterojunctions. The different thicknesses of the MoS₂ nanosheets on PSiNWs could change the energy levels of the conduction and valence bands, which has been shown in an earlier report.³⁸ Fig. 6c shows the dynamic response with different substrates, such as MoS₂/PSiNWs, MoS₂, and PSiNWs sensors. Among three sensors, MoS₂/PSiNWs showed the highest response to NO₂. Its response was nearly linear and increased by a factor of 2.3 in comparison to that of PSiNWs as

Fig. 6 NO₂ gas-sensing properties of MoS₂/PSiNW nanostructures with different thicknesses of MoS₂ nanosheets: (a) time-dependent gas-sensing behaviors toward different concentrations of NO₂; (b) the response as a function of gas concentration. The study of gas properties with different substrates: (c) dynamic response in different NO₂ concentrations; (d) response values of NO₂ concentrations.

shown in Fig. 6d. The formation of MoS₂/PSiNW heterojunctions has improved the gas sensing properties greatly.

Fig. 7a shows time-dependent gas-sensing behavior toward different concentrations of NO₂. Compared with S-1 and S-3, S-2 exhibited a higher sensitivity to NO₂. Moreover, S-1 and S-3 had no recovery at any cycle, while S-2 showed good recovery. The response value was further studied, and the results are shown in Fig. 7b. Compared with S-1 (6% to 50 ppm) and S-3 (7.7% to 50 ppm), S-2 (28.4% to 50 ppm) exhibited the highest response to NO₂ and increased by a factor of 4. This phenomenon is attributed to the decreased defects and grain boundaries. With increasing temperature from 720 °C to 820 °C, the chemical reaction was accelerated and the adsorption and diffusion of sulfur molecules at the interface were strengthened, which increased crystallite size and decreased the grain boundaries (see ESI†). Moreover, the number of defects would be decreased. The crystallite size of MoS₂ with the deposition temperature of 820 °C was too large, covering the surfaces of the MoS₂/PSiNWs and perturbing interfacial gas molecule diffusion considerably at the molecule surface. The device with deposition temperature of 720 °C could not react completely, resulting in unstable structures. This could be explained by the rapid transfer charge in MoS₂ and the high accumulation of electrons at the interface after increasing the annealing temperature.^{39,40} Therefore, the optimum deposition temperature was found to be 770 °C.

Fig. 8a shows the current–voltage (*I*–*V*) curves of the MoS₂/PSiNW heterojunction in dry air and NO₂ gas. The measurements were performed 60 min later after the device was put under the above conditions. The *I*–*V* curves exhibited good rectification characteristics at room temperature. The rectification ratio (*I*₊/*I*₋) at the voltage of ±5 V for this device was about 2.6.

The MoS₂–Ag contacts were ohmic in nature, therefore, the rectifying *I*–*V* characteristics were mainly attributed to the MoS₂/PSiNW heterojunction. When the air conditions were changed to NO₂, obvious changes in the *I*–*V* curves of the device were observed. As shown in the figure, the current decreased largely in both the forward and reverse directions. This demonstrates that the electrical properties of the junctions were dependent on NO₂. Thus, this MoS₂/PSiNW heterojunction device could function as a gas sensor. This is also confirmed in Table 1 by the comparison of the sensitivity to NO₂ of other sensors based on different MoS₂ nanostructures. The mechanism will be explained in detail later.

(c) Schematic illustration of the energy band of MoS₂/PSiNW heterojunction structures.

4.2. Gas sensing mechanism

The above-mentioned results reveal that the MoS₂/PSiNW heterojunctions exhibited good gas sensing properties to NO₂ at room temperature. The high sensitivity is due to the layered nanostructures that induce more active sites for the absorption of NO₂ and the modulation of changes to the band bending and depletion layer width at the interface. Moreover, MoS₂ has a remarkable concentration of S vacancies (5%).⁴⁸ When the sensor is exposed to nitrogen dioxide, NO₂ molecules act as electron acceptors and form NO₂[−] (ads) through capturing free electrons from the conduction band of the MoS₂ sheets. An electron depletion layer will be formed in the process, which leads to an increase in sensor resistance. When nitrogen gas

contacts surface of the sensor, N₂ molecules will react with nitrogen dioxide ions and release the trapped electrons back to the conduction band, decreasing the electron depletion layer width and increasing the resistance of the sensor. The reaction process can be shown as follows:

The work function and the band gap of n-Si are 4.21 and 1.12 eV, respectively, while the work function and the band gap of MoS₂ are 1.3 and 4.33 eV, respectively. The Fermi level of n-Si is higher than that of MoS₂ and thus the electrons transfer through the interface from n-Si to MoS₂ until their Fermi levels equalize, as shown in Fig. 8c. When the device is exposed to NO₂, larger amounts of NO₂ molecules are adsorbed on the surface of the MoS₂ film. Subsequently, some NO₂ molecules can be injected into the whole layers of film through the grain boundaries, and even reach the interface area of the junction. NO₂ captures free electrons from the conduction band of MoS₂ sheets, leading to a reduction in the charge carriers in it,^{49,50} and increasing the resistance of MoS₂. A depletion layer can be formed at the interface of MoS₂/PSiNWs. Moreover, the Fermi levels of the MoS₂ films shift toward the valence band as has been previously reported,⁵¹ and the energy barrier increases at the interface of MoS₂/PSiNWs. The sensing mechanism can be explained by the equivalent electrical circuit, as shown in Fig. 8b. The resistance of the MoS₂/PSiNW heterojunctions is composed of the resistance of the MoS₂ (R_{MoS_2}), the barrier (R_B) and the PSiNWs (R_{Si}).⁵² R_{Si} does not show any obvious change after exposure to NO₂ due to the heavy doping of Si (0.01–0.05 $\Omega \times \text{cm}$). R_{MoS_2} and R_B mainly determine the resistance variation of the MoS₂/PSiNW heterojunction. Fig. 8c shows an obvious potential barrier in the device. The properties of this barrier can greatly affect the resistance of the device as a result of its exponential relationship.⁵³ After adsorption, the charge transfer will lead to a low density of electrons on the MoS₂ side in the heterojunction, which increases the barrier of the heterojunction (R_B). This is confirmed by the I – V curve in Fig. 8a. It has been reported that the variation of barrier height and width due to gas adsorption can significantly change the resistance.^{54,55} Therefore, MoS₂/PSiNWs exhibit superior gas sensing properties compared to MoS₂ and PSiNW sensors (Fig. 6c).

Table 1 Comparison of the sensitivity to NO₂ gas of gas sensors based on different MoS₂ nanostructures and similar materials

Sensing material	Fabrication method	T (°C)	NO ₂ (ppm)	Response (%)	Reference
MoS ₂ /PSiNWs	Chemical etching + CVD	RT	50	28.4%	Present work
MoS ₂ film	CVD	RT	50	17.1%	41
rGO	Hydrolysis method	RT	50	10.8%	42
MoS ₂ /carbon nanotube	CVD	RT	50	12.6%	43
MoS ₂ /TiO ₂ nanotube	Anodization + hydrothermal method	150	50	14.2%	44
MoS ₂ /Au	Drop-coating	60	50	2.2	45
rGO/ZnO	Spraying	RT	50	3.05	46
rGO/TiO ₂	Hydrothermal method	RT	50	15.9	47

5. Conclusion

We demonstrate a new and simple fabrication method of MoS₂/PSiNW heterojunctions. In this approach, PSiNWs were obtained *via* Ag-assisted chemical etching, and then MoS₂ nanosheets were synthesized using sulfurization of direct-current (DC)-magnetic-sputtering Mo films on PSiNWs. The MoS₂/PSiNW heterojunctions exhibit superior gas sensing properties with a high response enhancement factor of ~2.3 at room temperature, in comparison with MoS₂ and PSiNWs. The MoS₂/PSiNWs-3 min with MoS₂ thickness of ~60 nm showed a maximum response of 28.4% to 50 ppm NO₂ and a highest limit of detection at 1 ppm. Additionally, MoS₂/PSiNWs fabricated using different deposition temperatures in the chemical vapor deposition (CVD) process were also measured and the results show that the optimum deposition temperature was 770 °C. The enhancement in gas sensing performances is attributed to the predominant geometrical morphology and effect of the depletion layer width at the interface. Moreover, a remarkable concentration of S vacancies in MoS₂ acted as independent active sites, magnifying the gas sensing properties of PSiNWs, by improving the interaction of molecules with defects. Therefore, MoS₂/PSiNW heterojunctions could stimulate greater innovation for future sensor technologies.
