Efficient photocatalysis with graphene oxide/Ag/Ag₂S–TiO₂ nanocomposites under visible light irradiation†

Shuang Shuang,^a Ruitao Lv,^b Xiaoyang Cui,^a Zheng Xie,^{ac} Jian Zheng^d and Zhengjun Zhang^{ib*}

Lack of visible light response and low quantum yield hinder the practical application of TiO₂ as a high-performance photocatalyst. Herein, we present a rational design of TiO₂ nanorod arrays (NRAs) decorated with Ag/Ag₂S nanoparticles (NPs) synthesized through successive ion layer adsorption and reaction (SILAR) and covered by graphene oxide (GO) at room temperature. Ag/Ag₂S NPs with uniform sizes are well-dispersed on the TiO₂ nanorods (NRs) as evidenced by electron microscopic analyses. The photocatalyst GO/Ag/Ag₂S decorated TiO₂ NRAs shows much higher visible light absorption response, which leads to remarkably enhanced photocatalytic activities on both dye degradation and photoelectrochemical (PEC) performance. Its photocatalytic reaction efficiency is 600% higher than that of pure TiO₂ sample under visible light. This remarkable enhancement can be attributed to a synergy of electron-sink function and surface plasmon resonance (SPR) of Ag NPs, band matching of Ag₂S NPs, and rapid charge carrier transport by GO, which significantly improves charge separation of the photoexcited TiO₂. The photocurrent density of GO/Ag/Ag₂S–TiO₂ NRAs reached to maximum (*i.e.* 6.77 mA cm^{−2} vs. 0 V). Our study proves that the rational design of composite nanostructures enhances the photocatalytic activity under visible light, and efficiently utilizes the complete solar spectrum for pollutant degradation.

Introduction

Heterogeneous photocatalysis of pollutants over semiconductor materials has recently emerged as an efficient method for purifying water and air. Among different semiconductors, TiO₂, usually as n-type semiconductor, is the most widely used photocatalyst due to its excellent photocatalytic activity, non-toxicity and good stability.^{1,2} However, the wide band gap (3.2 eV) of TiO₂ seriously limits its utilization under visible light which occupies a large portion of the solar spectrum. Till now, different methods such as metal decoration,^{3,4} metallic ion doping,⁵ non-metal doping,^{6,7} and dye sensitization^{8,9} have been proposed to modify and narrow its band gap, and enhance its photocatalytic activity under visible light radiation.^{10–12}

Decorating TiO₂ with metal, as one of the promising methods to develop highly efficient visible light photocatalysts,

is becoming attractive. The deposition of metal on TiO₂, as one of the ways to combine metal with TiO₂, can greatly improve its photo-efficiency through the Schottky barrier conduction band (CB) electron trapping and consequent longer electron–hole pair lifetime.^{3,13} Hu *et al.*¹⁴ reported a highly efficient Pt-decorated TiO₂ which demonstrates enhanced photocatalytic activity for NO_x oxidation under both UV and visible light irradiation. On the other hand, some noble metals such as Ag and Au, exhibit strong UV-vis absorption due to their plasmon resonance, produced by the collective oscillations of surface electrons.¹⁵

In other ways, coupling TiO₂ with different semiconductors is one of common ways to utilize the merit of various semiconductors and enhance the performance of photocatalysts.¹⁶ Some typical semiconductors like Ag₂S,¹⁷ GO,¹⁸ WO₃,¹⁹ AgVO₃,²⁰ and *et al.* Ag₂S as a typical n-type semiconductor, has low energy bandgap (about 1.0 eV) which enables it to absorb visible and near infrared (NIR) light without the necessity of further doping process. Moreover, quantum dots (QDs) of Ag₂S has attracted increasing research interest due to their low toxicity, narrow bandgap, and high absorption coefficient.²¹ So, it has been demonstrated that Ag₂S QDs could perform as a potential excellent visible and NIR photocatalyst.²²

Graphene oxide (GO) having sufficient reactive oxygen functional groups, is a good candidate for supporting metal or metal oxide particles. The existence of p-conjugation structure

and oxygen groups increases the photosensitivity of GO under visible light irradiation, and make it hydrophilic with good electronic performance. The electron energy gap of GO can be adjusted from 3.5 eV to 2.5 eV,^{23,24} depending directly on the oxidization degree of the graphene and the species of the oxygen groups. However, solo GO exhibits weak photocatalytic activity. Combining with other semiconductors could improve their property and prepare excellent photocatalysts. The pioneering work of Zhang *et al.*²⁵ on chemically bonded TiO₂ (P25)–graphene composite photocatalyst was firstly reported. They discovered high photocatalytic performance of the nanocomposite containing GO and TiO₂ (P25). Afterwards, there are many researches on the preparation of graphene–TiO₂ composite^{26–28} and its wide application such as photocatalytic bactericide,²⁹ hydrogen evolution,³⁰ or dye-sensitized solar cell.³¹ Such kind of composites owns at least two advantages: (1) controllable reduction of the GO nanosheets incorporated in the composition by using UV irradiation and (2) enhanced photocatalytic activity of TiO₂ thin films for higher efficiency of solar light irradiation. However, all the previous report about photocatalysts were usually powder and amorphous, which was difficult to handle and restricted its usage in practical applications.

In this work, we report a novel synthesis of TiO₂ NRAs on Si, quartz and F-doped SnO₂ (FTO) to form self-standing structures. The photocatalyst is much easier to recycle and extends its application. Besides, we tried to introduce Ag, Ag₂S and GO together according to the effects described in above description and prepare a unique photocatalyst with high activity. Based on our recent work on GO synthesis,³² a rational design of GO/Ag/Ag₂S–TiO₂ nanocomposite is proposed for highly efficient photocatalysis under visible light irradiation. In this regard, the effect of different combination among Ag NPs, Ag₂S NPs, GO and TiO₂ NRAs on degradation efficiency and photoelectrocatalytic property are discussed briefly.

Experimental methods

Synthesis of TiO₂ NRAs

The inclined TiO₂ NRAs were deposited by glancing angle deposition technique (GLAD) technique on different substrates and annealed as previously reported.³³ Before the deposition, the chamber was evacuated to a vacuum level above 1×10^{-8} Torr. During deposition, the vapor flux incident angle was set to $\sim 86^\circ$ off the surface normal to the substrates. And the deposition rate ($\sim 0.75 \text{ nm s}^{-1}$) and height of the NRs were monitored by a quartz crystal microbalance. Ti films were oxidized in a tube furnace in order to obtain TiO₂ NRAs. The Ti films were heated up to 400 °C for 2 h at a ramp of $5^\circ \text{C min}^{-1}$ under oxygen environment to obtain crystalline nanostructures for high photocatalytic activity.

Ag₂S NPs deposition on TiO₂ NRAs

Ag₂S NPs were deposited on TiO₂ NRs through successive ion layer adsorption and reaction (SILAR) method with slight modification as described in our previous work.¹⁵ Firstly, TiO₂

NRAs were immersed in 0.1 mg mL^{-1} AgNO₃ solution for 30 s, followed by rinsing with DI water and then immersed in Na₂S solution (12 mg mL^{-1}) for 30 s. After this, they were rinsed in DI water for several times. This SILAR process was repeated for several cycles until the desired quantity of decorated nanocrystallites was achieved.

Ag nanoparticles deposition on TiO₂ NRAs

Ag NPs were deposited using the same method. The NRs were immersed in 0.1 mg mL^{-1} AgNO₃ solution for 60 s, followed by rinsing with DI water and then immersed in NaBH₄ solution (1.0 mg mL^{-1}) for another 60 s, after which the resultant was rinsed with DI water for several times. This SILAR process was repeated for several cycles until the desired quantity of metallic nanocrystallites was achieved.

Ag/Ag₂S NPs deposition on TiO₂ NRAs

The TiO₂ NRAs were alternately coated with Ag and Ag₂S NPs respectively for specific times. To determine the optimal loading amounts of Ag and Ag₂S NPs decoration, the orthogonal experimental design was used, and results were shown in Table S1† (5 μM MO under visible light).

Combination with GO

GO was prepared *via* modified Hummers method. Typically, 5 g natural graphite flakes (Sigma Aldrich) and 3.0 g NaNO₃ was added to a 1000 mL beaker containing 150 mL concentrated sulphuric acid in an ice-bath and stirred for 1 h. Then 20 g KMnO₄ was gradually added while stirring, keeping the temperature below 30 °C. The mixture was stirred at room temperature for 24 h. Next, the beaker was placed in an ice bath and 300 mL DI water slowly added to the beaker, keeping the reaction temperature below 98 °C. After that, 30 mL H₂O₂ (30%) was added to the end reaction. Once H₂O₂ was added, the colour of the suspension turned bright yellow. The suspension was stirred for 30 min and then centrifuged at 8000 rpm to remove large flakes, then washed with 10% HCl solution, followed by washing with DI water and a three-week dialysis. Then Ag/Ag₂S–TiO₂ NRs with substrates were immersed in this solution for few seconds. The samples were dried in a muffle furnace at 50 °C for 2 hours to obtain the GO/Ag/Ag₂S–TiO₂ NRAs photocatalyst. GO–TiO₂ NRAs, GO/Ag–TiO₂ NRAs, GO/Ag₂S–TiO₂ NRAs were prepared in the similar way. The typical procedure were illustrated in Fig. 1(a).

Materials characterization

The morphology and nanostructure of the fabricated samples were examined by field-emission scanning electron microscope (FE-SEM, JEOL-7001F), high-resolution transmission electron microscope (HRTEM, JEOL-2011) and Raman spectroscopy (LABRAM HR800, excitation wavelength of 633 nm), respectively. A Rigaku 2500 X-ray diffractometer was used to investigate the crystallographic characteristics of samples. The optical properties of samples were examined by a UV-vis spectrometer (Perkin Elmer Lambda 35) in a wavelength range from 400 nm

Fig. 1 (a) Schematic illustration of the preparation of GO/Ag/Ag₂S–TiO₂ nanorod arrays (NRAs); scanning electron microscope (SEM) images of the different samples: (b) TiO₂ NRAs; (c) Ag–TiO₂ NRAs; (d) Ag₂S–TiO₂ NRAs; (e) Ag/Ag₂S–TiO₂ NRAs; (f) GO/Ag/Ag₂S–TiO₂ NRAs; (g) cross-section of sample GO/Ag/Ag₂S–TiO₂ NRAs.

to 900 nm at room temperature. The photoluminescence (PL) spectra were recorded by using Raman spectrometer (LabRAM ARMIS) with a 325 nm excitation. X-ray photoemission spectra were recorded by using ESCALAB 250Xi (Thermo Fisher). Monochromatized Al K α was employed as anode. Survey spectra of all the samples were recorded from 0 eV to 1350 eV (binding energy) with each step at 1.0 eV, while the spectra for every specific element were collected with 0.05 eV/step. Mass Spectrometer (MS) analysis was performed with equipment of Thermo Scientific Q Exactive mass spectrometer.

Photocatalytic degradation of crystal violet

The photocatalytic activity of different samples was evaluated by the photodegradation of crystal violet (CV) under visible light at ambient temperature. The sample on quartz substrate (15 mm \times 15 mm) was placed in a quartz cell containing 5 mL of CV (5 μ M) solution. Prior to light irradiation, the photocatalyst was immersed in a CV solution in dark for 30 min to reach an adsorption/desorption equilibrium, and Xe lamp with an ultraviolet filter was turned on for different time spans. After that, the concentration of CV was monitored using UV-vis spectroscopy at 584 nm. The degradation efficiency was calculated by $(1 - C/C_0) \times 100\%$.

Electrochemical measurements

The steady state current density and electrochemical impedance spectroscopy (EIS) measurements were carried out in a three-electrode-cell controlled by an electrochemistry workstation (CHI 660D, Chenhua instrument). The nanostructured films were used as a working electrode with an exposed area of 1.5 cm² in 0.1 M KOH solution (pH = 13.0). An Ag/AgCl electrode (saturated KCl) and Pt sheet were used as the reference and

counter electrodes, respectively. In this paper, all the reported potentials refer to the Ag/AgCl electrode. Before the electrochemical measurements, cyclic voltammetry tests were scanned for several cycles to confirm the stability of the samples. EIS spectra were recorded from 0.1 Hz to 10⁵ Hz at open circle potentials for all the samples under visible light irradiation (>420 nm). Photocurrent densities with bias in the range of –0.8–0.0 V were measured with and without the visible light.

Results and discussions

Characterization of photocatalysts

Fig. 1(b–g) show the scanning electron microscope (SEM) images of all the prepared samples. It can be seen that these TiO₂ NRAs regularly aligned on Si substrate having diameters of \sim 50 nm and lengths of \sim 200 nm (Fig. 1(b)). Ag and Ag₂S NPs distributes randomly on TiO₂ NRAs surface (Fig. 1(c–e)). GO of the sample GO/Ag/Ag₂S–TiO₂ NRAs, spreads smoothly like a blanket and covers Ag/Ag₂S–TiO₂ NRAs, which shows the connection of every single NRs to each other and with also some Ag and Ag₂S NPs (Fig. 1(f), (g)).

Moreover, transmission electron microscopy (TEM) images presented in Fig. 2 indicate Ag and Ag₂S NPs were separately dispersed on the surface of TiO₂. Their average sizes were about \sim 4 nm, having a regular elliptical shape. According to the measurement of lattice fringes, $d = 0.233$ nm, 0.244 nm, 0.345 nm and 0.325 nm match well with the crystallographic planes of Ag (111), Ag₂S (200), anatase (101) and rutile (110), respectively. The formation of metal–semiconductor nano-junctions, including Ag–TiO₂ NRAs, could be favorable for interfacial charge transfer among the three components, enhancing photocatalytic activities of the composites. In

Fig. 2 Transmission electron microscopy (TEM) images and high-resolution TEM (HRTEM) images of (a, b) Ag/Ag₂S-TiO₂ NRAs; (c, d) GO/Ag/Ag₂S-TiO₂ NRAs.

addition, the existence of anatase-rutile heterojunction in the NRAs could help the rutile particles to efficiently collect photon-induced electrons from the anatase particles to reduce the carrier recombination.³⁴

The Ti, Ag and S energy dispersive X-ray spectroscopy (EDX) element mapping of GO/Ag/Ag₂S-TiO₂ NRAs are shown in Fig. 3(a-d). The existence of Ag, S, Ti elements can be confirmed. Moreover, it can be concluded that Ag₂S NPs adhere on the surface of TiO₂ nanorods. X-ray diffraction (XRD) patterns of different samples are shown in Fig. 3(e). The spectra exhibited diffraction peaks at 25.5° and 27.6° corresponding to the (101) crystal planes of the anatase phase TiO₂.

Fig. 3 Morphology (a) and energy dispersive X-ray spectroscopy (EDX) elemental mapping of Ag/Ag₂S-TiO₂ NRAs sample: (b) Ti; (c) Ag; (d) S; (e) X-ray diffraction (XRD) patterns of the TiO₂ NRAs, Ag-TiO₂ NRAs, Ag₂S-TiO₂ NRAs, Ag/Ag₂S-TiO₂ NRAs and GO/Ag/Ag₂S-TiO₂ NRAs.

(JCPDS no. 21-1272) and (110) crystal planes of the rutile phase TiO₂ (JCPDS no. 21-1276). Beside this, the diffraction peak at 38.2° of Ag (111) (JCPDS no. 04-0783) can be found in the XRD patterns of Ag-TiO₂ NRAs, Ag/Ag₂S-TiO₂ NRAs, and GO/Ag/Ag₂S-TiO₂ NRAs. However, characteristic peaks of Ag₂S are very weak in all the samples. The intensive peak at 10.3° can be assigned to the (001) diffraction peak of graphene oxide. The full XRD spectrum of GO/Ag/Ag₂S-TiO₂ NRAs is shown in Fig. S1 as ESI.†

Fig. 4(a-e) are the O 1s, S 2p, Ag 3d, C 1s, Ti 2p X-ray photoelectron spectroscopy (XPS) fine scan spectra of GO/Ag/Ag₂S-TiO₂ NRAs. XPS surveys of all samples are shown in Fig. 4(g). The O 1s spectrum can be fitted by two peaks: main peak located at the binding energy 530.0 eV which can be attributed to the lattice 'O'; another one located at 531.3 eV referring to the hydroxyls or water adsorbed on the surface of the nanostructure. S 2p spectrum includes doublets containing S 2p_{3/2} and S 2p_{1/2} locating at 161.2 and 162.5 eV respectively, which can be assigned to S²⁻.³⁵ Ag 3d spectra can be deconvoluted into two sets of doublet (Ag 3d_{5/2} and Ag 3d_{3/2} with spin orbit splitting of 6.1 eV (ref. 36)): Ag 3d_{5/2} peaks at 368.3 eV for metallic Ag and 368.1 eV for Ag⁺.³⁷ C 1s spectra consist of the peaks at 284.9 eV, 286.3 eV and 288.9 eV, which are contributed by C-C; C-O and C=O bonds from deposited GO.³⁸ Ti 2p spectrum including doublets of Ti 2p_{3/2} and Ti 2p_{1/2} at binding energies 458.8 and 464.4 eV respectively confirm the presence of Ti⁴⁺ cations in TiO₂.

Diffusion reflectance UV-vis spectra of all typical resultants are shown in Fig. 4(f), which are fitted with Kubelka-Munk function. All the samples exhibit the absorption band around 400–900 nm. The spectra of Ag-TiO₂ NRAs, Ag₂S-TiO₂ NRAs and Ag/Ag₂S-TiO₂ NRAs demonstrate obvious enhancement on light absorption in the visible region compared with TiO₂ NRAs, implying the addition of Ag and Ag₂S can increase the adsorption efficiency for TiO₂. However, the surface plasmon

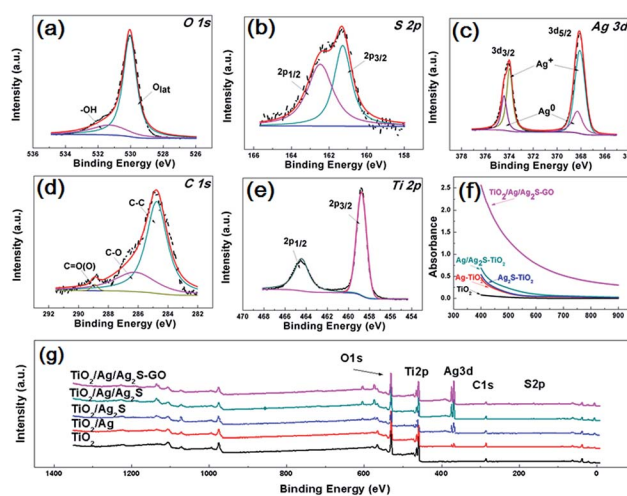

Fig. 4 X-ray photoelectron spectroscopy (XPS) spectra of all samples: (a) O 1s; (b) S 2p; (c) Ag 3d; (d) C 1s; (e) Ti 2p; (g) survey of GO/Ag/Ag₂S-TiO₂ NRAs; (f) diffusion reflectance UV-vis spectra of TiO₂ NRAs, Ag-TiO₂ NRAs, Ag₂S-TiO₂ NRAs, Ag/Ag₂S-TiO₂ NRAs and GO/Ag/Ag₂S-TiO₂ NRAs.

resonance (SPR) absorption band is hardly observed in the spectrum of Ag–TiO₂ NRAs because of the low imaginary part of the dielectric function of Ag. It can be clearly seen that the absorbance of GO/Ag/Ag₂S–TiO₂ NRAs is remarkably enhanced, which further confirms the contribution of GO for visible light utilization.

Photodegradation of CV

To evaluate the effect of composite decoration on the photocatalytic activity of TiO₂, the photodegradation of CV was carried out under visible light irradiation. For comparison, we also tested Ag/Ag₂S–TiO₂ NRAs, Ag–TiO₂ NRAs, Ag₂S–TiO₂ NRAs and TiO₂ NRAs. All these samples combined with GO were also tested. As shown in Table 1, after 120 min illumination under visible lights, neither TiO₂ NRAs nor GO–TiO₂ NRAs exhibited any activity for the CV degradation due to nonabsorbance of TiO₂ in visible light range, while 16.32%, 13.51% and 28.92% of CV were degraded by Ag–TiO₂ NRAs, Ag₂S–TiO₂ and Ag/Ag₂S–TiO₂ NRAs. These results indicated that both Ag and Ag₂S NPs could be excited by visible light. Ag NPs transform the irradiation photons energy into localized SPR oscillations and hot electrons move quickly to other part of nanostructured electrode.^{39–42} Higher activity of Ag/Ag₂S–TiO₂ NRAs could be attributed to the photoexcited Ag₂S semiconductor and plasmon-induced Ag NPs. Moreover, further enhancement of photocatalytic activities was observed after the introduction of GO. No matter what kind of combinations, after covering with GO, the photocatalytic degradation efficiencies were improved by 200–300%. With the combination of GO/Ag/Ag₂S–TiO₂ NRAs, the degradation efficiency of CV reached maximum to 80.01%. Therefore, GO played an important role in the enhanced activity of Ag/Ag₂S–TiO₂ NRAs.

Fig. 5 (a and b) show the comparison of the photocurrent density of different samples with light on/off under simulated solar irradiation. The photocurrent of pure TiO₂ was zero, while the photocurrent density of Ag–TiO₂ NRAs and Ag₂S–TiO₂ NRAs increased. And Ag/Ag₂S–TiO₂ NRAs raised to about 1.92 mA cm^{−2} at 0 V. After composited with GO, the photocurrent of GO/Ag/Ag₂S–TiO₂ NRAs was remarkably improved 10 times to 6.77 mA cm^{−2} at 0 V, which indicated that higher efficient separation of photo-generated carriers occurred. At the same condition, dark current density of GO/Ag/Ag₂S–TiO₂ NRAs (4.64 mA cm^{−2} at 0 V) was only 68% of that under visible light. Thus reasonable amount of GO in nanostructure could act as a sinker for photoinduced charge carriers, promoting charge separation to enhance the overall photocatalytic efficiency in contact with TiO₂. The promotion could be contributed to the addition of p-type semiconductor of GO which has hollow sites.¹⁴ In the GO/Ag/Ag₂S–TiO₂ NRAs sample, Ag₂S and TiO₂ are both n-type,⁴³ the introduction of GO

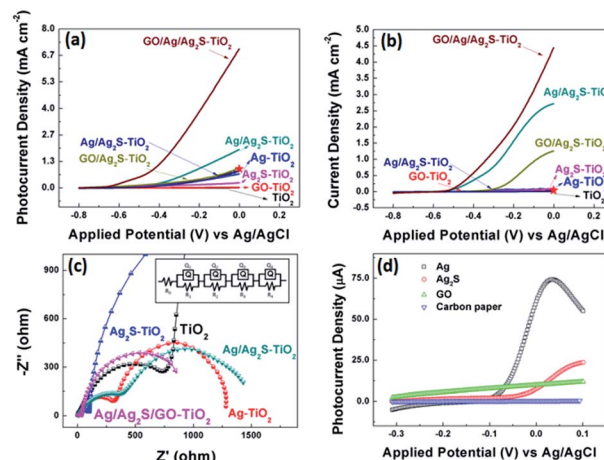

Fig. 5 (a) j – V characteristics of all samples under visible light illuminations; (b) j – V characteristics of all samples without light illuminations. The red stars in (a, b) indicate the current density of TiO₂/rGO/NiFe–LDH NRAs reported by Ning *et al.* under same voltage condition;³⁶ (c) partial enlarged detail Nyquist plots under visible light at open circuit voltage of all decorated sample and the equivalent circuit for samples; (d) j – V characteristics for various combination of Ag, Ag₂S and GO decoration on carbon paper under visible light illuminations.

will compose p–n junction in the sample, then the junction could enhance the current transferring through the electron and hole sites among the composites of the sample. Ning *et al.* have reported a core–shell heterostructure TiO₂/rGO/NiFe–LDH NRAs which own an enhanced photoconversion efficiency (0.58% at 0.13 V vs. SCE) and photocurrent density (1.74 mA cm^{−2} at 0.6 V vs. SCE).⁴⁴ For comparison, we plot current value at same voltage as red star on our PEC figures. Moreover, in site doped Au/TiO₂ nanotube photoanode made by Wu,⁴⁵ and GO-coated TiO₂ nanoparticles fabricated by Kim *et al.*⁴⁶ were all tested by photocurrent. The relative datas were organized in Table 2. Compared with recent results, our material's performance on separation of electrons and holes make a quite big progress.

EIS measurements for all samples were also conducted under visible light irradiation, as shown in Fig. 5(c) as the enlarged image of full spectra (see Fig. S2†). This method can characterize the charge-carrier migration. An equivalent circuit was used to fit the Nyquist plots as shown in the inset of Fig. 5(c) and simulated data were shown in Table S2.† All the hybrid nanostructured samples showed depressed semicircles at high frequencies compared with pure TiO₂ counterparts. The reduced semicircles indicate diminished resistance of working electrodes, suggesting a decrease in the solid state interface layer resistance and the charge transfer resistance across the solid–liquid junction on the surface by forming hybrid structures of decorated TiO₂ NRAs with GO.⁴⁷ The R_0 are the

resistance of FTO substrate. Q_1 and R_1 represent the double layer on the reference electrode. The obtained Nyquist spectra show two arcs, the first arc (R_2), at higher frequencies, is related to the interfacial resistance between TiO₂ nanorod array and electrolyte. And the arcs at the intermediate frequencies represent the resistance (R_3) of holes transferred to the electrolyte through surface states (such as Ag or Ag₂S NPs) and the capacitance of surface states. For Ag/Ag₂S-TiO₂ NRAs, Ag NPs was deposited after Ag₂S decoration.

However, based on HRTEM analysis, the Ag and Ag₂S are separately attached on the TiO₂ arrays surface. So, an extra resistance (R_4) was added and can be described as electron or hole transfer between NPs of Ag and Ag₂S. When layer of GO was coated, the R_4 can also represents the transfer between the decorated TiO₂ and GO. All simulated data are listed in Table S2.†⁴⁸ Based on the results, it can be seen that the additions of Ag or/and Ag₂S can decrease the R_2 and R_3 , implying the reduced transferring resistance between the deposition substrate and TiO₂. The extra introduction of GO can decrease the hole transfer resistance (R_3) dramatically. By comparing the EIS data, GO/Ag/Ag₂S-TiO₂ NRAs are superior to other samples with smaller semicircles, suggesting a rapid transport of charge carriers and an effective charge separation, which is in agreement with the PEC analysis.

In the photocurrent measurements, the obtained currents tested under visible light include photocurrent for oxygen evolution reaction (OER), and electrochemical current caused by applied potential in OER process. So, we use current with light minus the one without light in order to investigate more specific on photo-catalysis progress. Then, the largest current value obtained on GO/Ag/Ag₂S-TiO₂ NRAs was used as reference. The currents of all the other samples were divided by the reference to calculate the relative values, which are listed in Table 3. According to data, it can be easily obtained that simply composing between Ag and Ag₂S particles doesn't improve the photocatalytic performance so much. Only after the addition of GO layer, the activities of all system enhance remarkably, while the GO/Ag/Ag₂S-TiO₂ NRAs has maximum increment up to 7.7 times. GO layer could both enhanced transmission of charges and protect NPs from corrosion. What's more, to confirm the reaction mechanism and active reaction sites among all the possible composites, we

deposited the single composite on carbon paper rather than TiO₂ NRAs. Then the photocurrents of the prepared samples were recorded under the same test condition which are shown in Fig. 5(d). Basing on the tests, the onset potentials of Ag is most negative among all the prepared samples, implying that Ag has lowest OER overpotential among the four species.

The evolution of the CV solution's absorption spectra for GO/Ag/Ag₂S-TiO₂ NRAs are recorded during the whole reaction process every 30 min time point. From Fig. 6(a), the intensity of peak gradually declines with longer irradiation time which indicates reduced concentrate of dye concentrate. To analyse the products after reaction, mass spectrometer (MS) for CV in aqueous solution before and after prolonged irradiation (120 min) are also studied, shown in Fig. S3.† As standard CV molecular ($M = 407.99$) concerned, peak at $m/z = 372.23$ indicate CV molecular which equals to formula weight minus chloridion. When we infer product after reaction from $m/z = 152.12$, it is exactly coincident to 1/3 part of whole molecular that three C-C bonds of C atom in central broken up. The result means there is a single product after degradation reaction.

Photoluminescence (PL) technique is an effective way to study the efficiency of the charge carrier trapping, migration and transfer, as PL signals result from the recombination of photo-induced carriers. Fig. 6(b) presents the PL spectra of all test samples. The peaks at ~515 nm can be attributed to the self-trapped excitations and the oxygen vacancies (V_o) in TiO₂.^{49,50} Due to the metallic particle decoration on TiO₂, the PL peaks of TiO₂ become weaker. The PL intensity of GO/Ag/Ag₂S-TiO₂ NRAs is much lower than that of other nanostructures, implying a lower recombination rate of photo-induced electron-hole pairs, and thus a better photocatalytic performance. While PL intensity of Ag-TiO₂ NRAs, Ag₂S-TiO₂ NRAs and Ag/Ag₂S-TiO₂ NRAs are between TiO₂ NRAs and GO/Ag/Ag₂S-TiO₂ NRAs which is corresponding with dye degradation results.

Photocatalytic mechanism

Basing on above results, the photocatalytic mechanism of GO/Ag/Ag₂S-TiO₂ NRAs can be proposed as below. The valence band-edges of materials are shown in Fig. 6(c). In the composite, Ag NPs, Ag₂S NPs (always n-type) and GO sheets

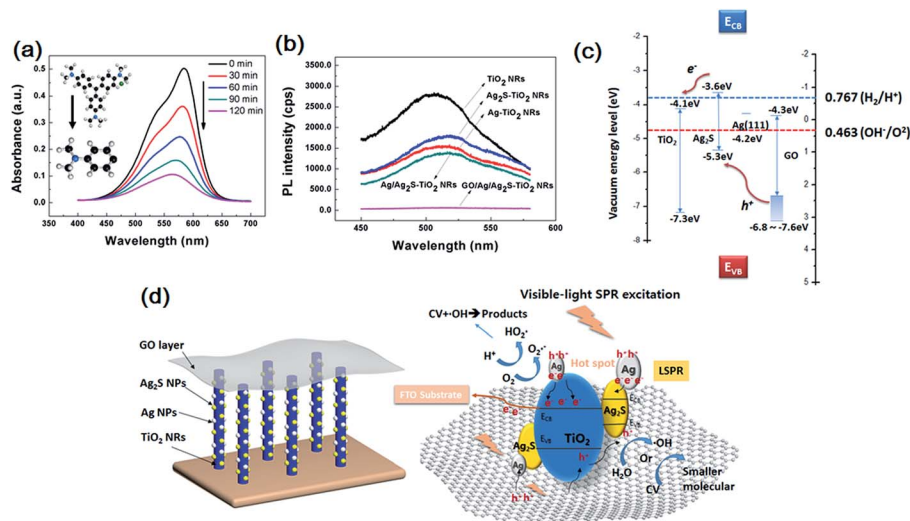

Fig. 6 (a) UV-visible absorption spectra recorded during the catalytic degradation of CV over GO/Ag/Ag₂S-TiO₂ NRAs; (b) photoluminescence (PL) spectrum of single TiO₂ NRAs, Ag-TiO₂ NRAs, Ag₂S-TiO₂ NRAs, Ag/Ag₂S-TiO₂ NRAs and GO/Ag/Ag₂S-TiO₂ NRAs; (c) band edge positions of TiO₂, Ag₂S, Ag and GO; (d) photocatalytic process for GO/Ag/Ag₂S-TiO₂ NRAs under visible light.

(typical p-type) are active to visible light. The higher activity of GO/Ag/Ag₂S-TiO₂ NRs could be contributed to the photoexcited.

Ag₂S semiconductor, plasmon-induced Ag NPs, effective electron-hole separation of GO and clever combination of all the composites. Under visible light irradiation, Ag nanoparticles are photoexcited owing to their SPR effect, and then charge separation is accomplished, where the electrons transfer from Ag nanoparticles to the TiO₂ CB, leading to the generation of holes in Ag nanoparticles for oxidation of OH⁻. Meanwhile, Ag₂S NPs and GO are also excited to form electrons and holes.⁵¹ Considering that the CB of Ag₂S is more positive than that of TiO₂,^{52,53} electrons generated from Ag₂S also tend to transfer into the CB of TiO₂. This facilitates the separation of electrons and holes. Besides, covering of GO layer remarkably enhances full-wavelength absorption from UV-vis spectra reported in Fig. 4(f), which accomplishes high-usage of visible light. Since work electrode surface is positively charged, excited electrons from GO are easier to move into TiO₂. Then, vast holes tend to move directly into Ag NPs which consume holes quickly because of its lowest OER overpotential among the four species in the composite, resulting acceleration of the whole reaction. Thus Ag NPs is probably active OER reaction sites for the whole system. Ag nanoparticles also act as the charge transmission bridges, which can efficiently promote the separation of electron-hole pairs. Also, both Ag and Ag₂S combination with TiO₂ could narrow down its original band gap, it may enhance the adsorption efficiency of the composite.

Then electrons can either reduce the dye or can react with electron acceptors (O₂ absorbed on the surface of Ti³⁺ or dissolved in water) to create superoxide radicals (O₂^{•-}). Meanwhile, the resultant electron-deficient Ag particles can oxidize the organic molecule or react with OH⁻ to form hydroxyl radicals, OH[•]. The process is demonstrated in Fig. 6(d). The co-decoration of Ag/Ag₂S NPs and GO not only extends TiO₂ to visible light region, but also increases the efficiency of charge separation and improves its photocatalytic efficiency.

Conclusions

In summary, we obtained the procedure for preparation of the TiO₂ NRAs on various substrates including FTO, Si and *et al.*, and fabricated successfully GO/Ag/Ag₂S-TiO₂ NRAs by using SILAR technique and impregnation method. By comparing with TiO₂ NRAs, it exhibits remarkable improvement of photocatalytic activity for dye degradation and PEC performance. The enhanced photocatalytic activities through decoration of the NRAs are attributed to the synergy of matched band of Ag₂S NPs, SPR effect of Ag NPs and rapid transport of charge carriers that improves charge separation of system. Our studies demonstrate that we can utilize photon in a wider range of solar spectrum to generate charge carriers for photocatalytic reactions through rational design of composite nanostructures. The combination of GO with traditional photocatalyst also provides a more effective way to harvest solar energy for decomposition reaction.
