# Efficient photocatalysis with graphene oxide/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> nanocomposites under visible light irradiation†

Shuang Shuang,<sup>a</sup> Ruitao Lv,<sup>b</sup> Xiaoyang Cui,<sup>a</sup> Zheng Xie,<sup>ac</sup> Jian Zheng<sup>d</sup> and Zhengjun Zhang<sup>id</sup>\*<sup>b</sup>

Lack of visible light response and low quantum yield hinder the practical application of TiO<sub>2</sub> as a high-performance photocatalyst. Herein, we present a rational design of TiO<sub>2</sub> nanorod arrays (NRAs) decorated with Ag/Ag<sub>2</sub>S nanoparticles (NPs) synthesized through successive ion layer adsorption and reaction (SILAR) and covered by graphene oxide (GO) at room temperature. Ag/Ag<sub>2</sub>S NPs with uniform sizes are well-dispersed on the TiO<sub>2</sub> nanorods (NRs) as evidenced by electron microscopic analyses. The photocatalyst GO/Ag/Ag<sub>2</sub>S decorated TiO<sub>2</sub> NRAs shows much higher visible light absorption response, which leads to remarkably enhanced photocatalytic activities on both dye degradation and photoelectrochemical (PEC) performance. Its photocatalytic reaction efficiency is 600% higher than that of pure TiO<sub>2</sub> sample under visible light. This remarkable enhancement can be attributed to a synergy of electron-sink function and surface plasmon resonance (SPR) of Ag NPs, band matching of Ag<sub>2</sub>S NPs, and rapid charge carrier transport by GO, which significantly improves charge separation of the photoexcited TiO<sub>2</sub>. The photocurrent density of GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs reached to maximum (*i.e.* 6.77 mA cm<sup>-2</sup> vs. 0 V). Our study proves that the rational design of composite nanostructures enhances the photocatalytic activity under visible light, and efficiently utilizes the complete solar spectrum for pollutant degradation.

## Introduction

Heterogeneous photocatalysis of pollutants over semiconductor materials has recently emerged as an efficient method for purifying water and air. Among different semiconductors, TiO<sub>2</sub>, usually as n-type semiconductor, is the most widely used photocatalyst due to its excellent photocatalytic activity, non-toxicity and good stability.<sup>1,2</sup> However, the wide band gap (3.2 eV) of TiO<sub>2</sub> seriously limits its utilization under visible light which occupies a large portion of the solar spectrum. Till now, different methods such as metal decoration,<sup>3,4</sup> metallic ion doping,<sup>5</sup> non-metal doping,<sup>6,7</sup> and dye sensitization<sup>8,9</sup> have been proposed to modify and narrow its band gap, and enhance its photocatalytic activity under visible light radiation.<sup>10–12</sup>

Decorating TiO<sub>2</sub> with metal, as one of the promising methods to develop highly efficient visible light photocatalysts,

is becoming attractive. The deposition of metal on TiO<sub>2</sub>, as one of the ways to combine metal with TiO<sub>2</sub>, can greatly improve its photo-efficiency through the Schottky barrier conduction band (CB) electron trapping and consequent longer electron–hole pair lifetime.<sup>3,13</sup> Hu *et al.*<sup>14</sup> reported a highly efficient Pt-decorated TiO<sub>2</sub> which demonstrates enhanced photocatalytic activity for NO<sub>x</sub> oxidation under both UV and visible light irradiation. On the other hand, some noble metals such as Ag and Au, exhibit strong UV-vis absorption due to their plasmon resonance, produced by the collective oscillations of surface electrons.<sup>15</sup>

In other ways, coupling TiO<sub>2</sub> with different semiconductors is one of common ways to utilize the merit of various semiconductors and enhance the performance of photocatalysts.<sup>16</sup> Some typical semiconductors like Ag<sub>2</sub>S,<sup>17</sup> GO,<sup>18</sup> WO<sub>x</sub>,<sup>19</sup> AgVO<sub>x</sub><sup>20</sup> and *et al.* Ag<sub>2</sub>S as a typical n-type semiconductor, has low energy bandgap (about 1.0 eV) which enables it to absorb visible and near infrared (NIR) light without the necessity of further doping process. Moreover, quantum dots (QDs) of Ag<sub>2</sub>S has attracted increasing research interest due to their low toxicity, narrow bandgap, and high absorption coefficient.<sup>21</sup> So, it has been demonstrated that Ag<sub>2</sub>S QDs could perform as a potential excellent visible and NIR photocatalyst.<sup>22</sup>

Graphene oxide (GO) having sufficient reactive oxygen functional groups, is a good candidate for supporting metal or metal oxide particles. The existence of p-conjugation structure

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c7ra13501g

and oxygen groups increases the photosensitivity of GO under visible light irradiation, and make it hydrophilic with good electronic performance. The electron energy gap of GO can be adjusted from 3.5 eV to 2.5 eV,<sup>23,24</sup> depending directly on the oxidization degree of the graphene and the species of the oxygen groups. However, solo GO exhibits weak photocatalytic activity. Combining with other semiconductors could improve their property and prepare excellent photocatalysts. The pioneering work of Zhang *et al.*<sup>25</sup> on chemically bonded TiO<sub>2</sub> (P25)–graphene composite photocatalyst was firstly reported. They discovered high photocatalytic performance of the nanocomposite containing GO and TiO<sub>2</sub> (P25). Afterwards, there are many researches on the preparation of graphene–TiO<sub>2</sub> composite<sup>26–28</sup> and its wide application such as photocatalytic bactericide,<sup>29</sup> hydrogen evolution,<sup>30</sup> or dye-sensitized solar cell.<sup>31</sup> Such kind of composites owns at least two advantages: (1) controllable reduction of the GO nanosheets incorporated in the composition by using UV irradiation and (2) enhanced photocatalytic activity of TiO<sub>2</sub> thin films for higher efficiency of solar light irradiation. However, all the previous report about photocatalysts were usually powder and amorphous, which was difficult to handle and restricted its usage in practical applications.

In this work, we report a novel synthesis of TiO<sub>2</sub> NRAs on Si, quartz and F-doped SnO<sub>2</sub> (FTO) to form self-standing structures. The photocatalyst is much easier to recycle and extends its application. Besides, we tried to introduce Ag, Ag<sub>2</sub>S and GO together according to the effects described in above description and prepare a unique photocatalyst with high activity. Based on our recent work on GO synthesis,<sup>32</sup> a rational design of GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> nanocomposite is proposed for highly efficient photocatalysis under visible light irradiation. In this regard, the effect of different combination among Ag NPs, Ag<sub>2</sub>S NPs, GO and TiO<sub>2</sub> NRAs on degradation efficiency and photoelectrocatalytic property are discussed briefly.

## Experimental methods

### Synthesis of TiO<sub>2</sub> NRAs

The inclined TiO<sub>2</sub> NRAs were deposited by glancing angle deposition technique (GLAD) technique on different substrates and annealed as previously reported.<sup>33</sup> Before the deposition, the chamber was evacuated to a vacuum level above  $1 \times 10^{-8}$  Torr. During deposition, the vapor flux incident angle was set to  $\sim 86^\circ$  off the surface normal to the substrates. And the deposition rate ( $\sim 0.75 \text{ nm s}^{-1}$ ) and height of the NRs were monitored by a quartz crystal microbalance. Ti films were oxidized in a tube furnace in order to obtain TiO<sub>2</sub> NRAs. The Ti films were heated up to 400 °C for 2 h at a ramp of  $5 \text{ }^\circ\text{C min}^{-1}$  under oxygen environment to obtain crystalline nanostructures for high photocatalytic activity.

### Ag<sub>2</sub>S NPs deposition on TiO<sub>2</sub> NRAs

Ag<sub>2</sub>S NPs were deposited on TiO<sub>2</sub> NRs through successive ion layer adsorption and reaction (SILAR) method with slight modification as described in our previous work.<sup>15</sup> Firstly, TiO<sub>2</sub>

NRAs were immersed in  $0.1 \text{ mg mL}^{-1}$  AgNO<sub>3</sub> solution for 30 s, followed by rinsing with DI water and then immersed in Na<sub>2</sub>S solution ( $12 \text{ mg mL}^{-1}$ ) for 30 s. After this, they were rinsed in DI water for several times. This SILAR process was repeated for several cycles until the desired quantity of decorated nanocrystallites was achieved.

### Ag nanoparticles deposition on TiO<sub>2</sub> NRAs

Ag NPs were deposited using the same method. The NRs were immersed in  $0.1 \text{ mg mL}^{-1}$  AgNO<sub>3</sub> solution for 60 s, followed by rinsing with DI water and then immersed in NaBH<sub>4</sub> solution ( $1.0 \text{ mg mL}^{-1}$ ) for another 60 s, after which the resultant was rinsed with DI water for several times. This SILAR process was repeated for several cycles until the desired quantity of metallic nanocrystallites was achieved.

### Ag/Ag<sub>2</sub>S NPs deposition on TiO<sub>2</sub> NRAs

The TiO<sub>2</sub> NRAs were alternately coated with Ag and Ag<sub>2</sub>S NPs respectively for specific times. To determine the optimal loading amounts of Ag and Ag<sub>2</sub>S NPs decoration, the orthogonal experimental design was used, and results were shown in Table S1† (5 μM MO under visible light).

### Combination with GO

GO was prepared *via* modified Hummers method. Typically, 5 g natural graphite flakes (Sigma Aldrich) and 3.0 g NaNO<sub>3</sub> was added to a 1000 mL beaker containing 150 mL concentrated sulphuric acid in an ice-bath and stirred for 1 h. Then 20 g KMnO<sub>4</sub> was gradually added while stirring, keeping the temperature below 30 °C. The mixture was stirred at room temperature for 24 h. Next, the beaker was placed in an ice bath and 300 mL DI water slowly added to the beaker, keeping the reaction temperature below 98 °C. After that, 30 mL H<sub>2</sub>O<sub>2</sub> (30%) was added to the end reaction. Once H<sub>2</sub>O<sub>2</sub> was added, the colour of the suspension turned bright yellow. The suspension was stirred for 30 min and then centrifuged at 8000 rpm to remove large flakes, then washed with 10% HCl solution, followed by washing with DI water and a three-week dialysis. Then Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRs with substrates were immersed in this solution for few seconds. The samples were dried in a muffle furnace at 50 °C for 2 hours to obtain the GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs photocatalyst. GO–TiO<sub>2</sub> NRAs, GO/Ag–TiO<sub>2</sub> NRAs, GO/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs were prepared in the similar way. The typical procedure were illustrated in Fig. 1(a).

### Materials characterization

The morphology and nanostructure of the fabricated samples were examined by field-emission scanning electron microscope (FE-SEM, JEOL-7001F), high-resolution transmission electron microscope (HRTEM, JEOL-2011) and Raman spectroscopy (LABRAM HR800, excitation wavelength of 633 nm), respectively. A Rigaku 2500 X-ray diffractometer was used to investigate the crystallographic characteristics of samples. The optical properties of samples were examined by a UV-vis spectrometer (Perkin Elmer Lambda 35) in a wavelength range from 400 nm

Fig. 1 (a) Schematic illustration of the preparation of GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> nanorod arrays (NRAs); scanning electron microscope (SEM) images of the different samples: (b) TiO<sub>2</sub> NRAs; (c) Ag-TiO<sub>2</sub> NRAs; (d) Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs; (e) Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs; (f) GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs; (g) cross-section of sample GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs.

to 900 nm at room temperature. The photoluminescence (PL) spectra were recorded by using Raman spectrometer (LabRAM ARMIS) with a 325 nm excitation. X-ray photoemission spectra were recorded by using ESCALAB 250Xi (Thermo Fisher). Monochromatized Al K $\alpha$  was employed as anode. Survey spectra of all the samples were recorded from 0 eV to 1350 eV (binding energy) with each step at 1.0 eV, while the spectra for every specific element were collected with 0.05 eV/step. Mass Spectrometer (MS) analysis was performed with equipment of Thermo Scientific Q Exactive mass spectrometer.

### Photocatalytic degradation of crystal violet

The photocatalytic activity of different samples was evaluated by the photodegradation of crystal violet (CV) under visible light at ambient temperature. The sample on quartz substrate (15 mm  $\times$  15 mm) was placed in a quartz cell containing 5 mL of CV (5  $\mu$ M) solution. Prior to light irradiation, the photocatalyst was immersed in a CV solution in dark for 30 min to reach an adsorption/desorption equilibrium, and Xe lamp with an ultraviolet filter was turned on for different time spans. After that, the concentration of CV was monitored using UV-vis spectroscopy at 584 nm. The degradation efficiency was calculated by  $(1 - C/C_0) \times 100\%$ .

### Electrochemical measurements

The steady state current density and electrochemical impedance spectroscopy (EIS) measurements were carried out in a three-electrode-cell controlled by an electrochemistry workstation (CHI 660D, Chenhua instrument). The nanostructured films were used as a working electrode with an exposed area of 1.5 cm<sup>2</sup> in 0.1 M KOH solution (pH = 13.0). An Ag/AgCl electrode (saturated KCl) and Pt sheet were used as the reference and

counter electrodes, respectively. In this paper, all the reported potentials refer to the Ag/AgCl electrode. Before the electrochemical measurements, cyclic voltammetry tests were scanned for several cycles to confirm the stability of the samples. EIS spectra were recorded from 0.1 Hz to 10<sup>5</sup> Hz at open circle potentials for all the samples under visible light irradiation (>420 nm). Photocurrent densities with bias in the range of -0.8-0.0 V were measured with and without the visible light.

## Results and discussions

### Characterization of photocatalysts

Fig. 1(b-g) show the scanning electron microscope (SEM) images of all the prepared samples. It can be seen that these TiO<sub>2</sub> NRAs regularly aligned on Si substrate having diameters of  $\sim$ 50 nm and lengths of  $\sim$ 200 nm (Fig. 1(b)). Ag and Ag<sub>2</sub>S NPs distributes randomly on TiO<sub>2</sub> NRAs surface (Fig. 1(c-e)). GO of the sample GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs, spreads smoothly like a blanket and covers Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs, which shows the connection of every single NRs to each other and with also some Ag and Ag<sub>2</sub>S NPs (Fig. 1(f), (g)).

Moreover, transmission electron microscopy (TEM) images presented in Fig. 2 indicate Ag and Ag<sub>2</sub>S NPs were separately dispersed on the surface of TiO<sub>2</sub>. Their average sizes were about  $\sim$ 4 nm, having a regular elliptical shape. According to the measurement of lattice fringes,  $d = 0.233$  nm, 0.244 nm, 0.345 nm and 0.325 nm match well with the crystallographic planes of Ag (111), Ag<sub>2</sub>S (200), anatase (101) and rutile (110), respectively. The formation of metal-semiconductor nano-junctions, including Ag-TiO<sub>2</sub> NRAs, could be favorable for interfacial charge transfer among the three components, enhancing photocatalytic activities of the composites. In

Fig. 2 Transmission electron microscopy (TEM) images and high-resolution TEM (HRTEM) images of (a, b) Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs; (c, d) GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs.

addition, the existence of anatase–rutile heterojunction in the NRAs could help the rutile particles to efficiently collect photon-induced electrons from the anatase particles to reduce the carrier recombination.<sup>34</sup>

The Ti, Ag and S energy dispersive X-ray spectroscopy (EDX) element mapping of GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs are shown in Fig. 3(a–d). The existence of Ag, S, Ti elements can be confirmed. Moreover, it can be concluded that Ag<sub>2</sub>S NPs adhere on the surface of TiO<sub>2</sub> nanorods. X-ray diffraction (XRD) patterns of different samples are shown in Fig. 3(e). The spectra exhibited diffraction peaks at 25.5° and 27.6° corresponding to the (101) crystal planes of the anatase phase TiO<sub>2</sub>

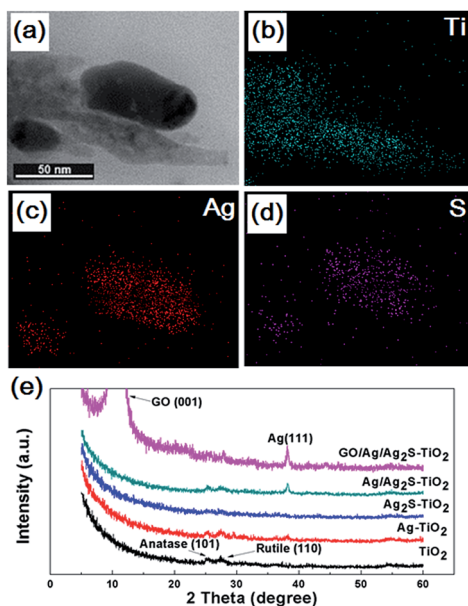

Fig. 3 Morphology (a) and energy dispersive X-ray spectroscopy (EDX) elemental mapping of Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs sample: (b) Ti; (c) Ag; (d) S; (e) X-ray diffraction (XRD) patterns of the TiO<sub>2</sub> NRAs, Ag–TiO<sub>2</sub> NRAs, Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs, Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs and GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs.

(JCPDS no. 21-1272) and (110) crystal planes of the rutile phase TiO<sub>2</sub> (JCPDS no. 21-1276). Beside this, the diffraction peak at 38.2° of Ag (111) (JCPDS no. 04-0783) can be found in the XRD patterns of Ag–TiO<sub>2</sub> NRAs, Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs, and GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs. However, characteristic peaks of Ag<sub>2</sub>S are very weak in all the samples. The intensive peak at 10.3° can be assigned to the (001) diffraction peak of graphene oxide. The full XRD spectrum of GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs is shown in Fig. S1 as ESI.†

Fig. 4(a–e) are the O 1s, S 2p, Ag 3d, C 1s, Ti 2p X-ray photoelectron spectroscopy (XPS) fine scan spectra of GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs. XPS surveys of all samples are shown in Fig. 4(g). The O 1s spectrum can be fitted by two peaks: main peak located at the binding energy 530.0 eV which can be attributed to the lattice ‘O’; another one located at 531.3 eV referring to the hydroxyls or water adsorbed on the surface of the nanostructure. S 2p spectrum includes doublets containing S 2p<sub>3/2</sub> and S 2p<sub>1/2</sub> locating at 161.2 and 162.5 eV respectively, which can be assigned to S<sup>2–</sup>.<sup>35</sup> Ag 3d spectra can be deconvoluted into two sets of doublet (Ag 3d<sub>5/2</sub> and Ag 3d<sub>3/2</sub> with spin orbit splitting of 6.1 eV (ref. 36)): Ag 3d<sub>5/2</sub> peaks at 368.3 eV for metallic Ag and 368.1 eV for Ag<sup>+</sup>.<sup>37</sup> C 1s spectra consist of the peaks at 284.9 eV, 286.3 eV and 288.9 eV, which are contributed by C–C; C–O and C=O bonds from deposited GO.<sup>38</sup> Ti 2p spectrum including doublets of Ti 2p<sub>3/2</sub> and Ti 2p<sub>1/2</sub> at binding energies 458.8 and 464.4 eV respectively confirm the presence of Ti<sup>4+</sup> cations in TiO<sub>2</sub>.

Diffusion reflectance UV-vis spectra of all typical resultants are shown in Fig. 4(f), which are fitted with Kubelka–Munk function. All the samples exhibit the absorption band around 400–900 nm. The spectra of Ag–TiO<sub>2</sub> NRAs, Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs and Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs demonstrate obvious enhancement on light absorption in the visible region compared with TiO<sub>2</sub> NRAs, implying the addition of Ag and Ag<sub>2</sub>S can increase the adsorption efficiency for TiO<sub>2</sub>. However, the surface plasmon

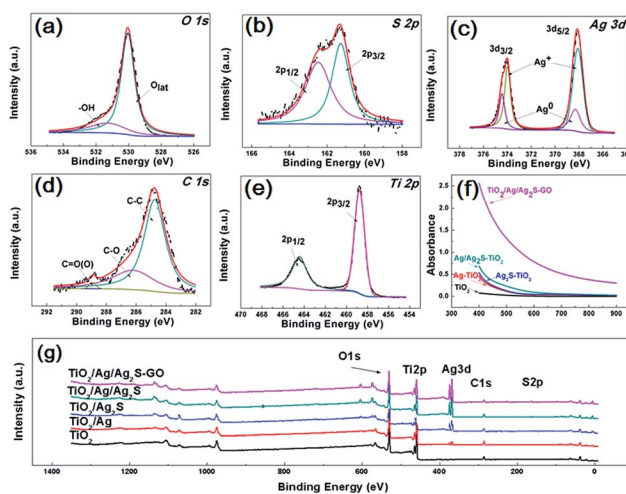

Fig. 4 X-ray photoelectron spectroscopy (XPS) spectra of all samples: (a) O 1s; (b) S 2p; (c) Ag 3d; (d) C 1s; (e) Ti 2p; (g) survey of GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs; (f) diffusion reflectance UV-vis spectra of TiO<sub>2</sub> NRAs, Ag–TiO<sub>2</sub> NRAs, Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs, Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs and GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs.

resonance (SPR) absorption band is hardly observed in the spectrum of Ag-TiO<sub>2</sub> NRAs because of the low imaginary part of the dielectric function of Ag. It can be clearly seen that the absorbance of GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs is remarkably enhanced, which further confirms the contribution of GO for visible light utilization.

### Photodegradation of CV

To evaluate the effect of composite decoration on the photocatalytic activity of TiO<sub>2</sub>, the photodegradation of CV was carried out under visible light irradiation. For comparison, we also tested Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs, Ag-TiO<sub>2</sub> NRAs, Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs and TiO<sub>2</sub> NRAs. All these samples combined with GO were also tested. As shown in Table 1, after 120 min illumination under visible lights, neither TiO<sub>2</sub> NRAs nor GO-TiO<sub>2</sub> NRAs exhibited any activity for the CV degradation due to nonabsorbance of TiO<sub>2</sub> in visible light range, while 16.32%, 13.51% and 28.92% of CV were degraded by Ag-TiO<sub>2</sub> NRAs, Ag<sub>2</sub>S-TiO<sub>2</sub> and Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs. These results indicated that both Ag and Ag<sub>2</sub>S NPs could be excited by visible light. Ag NPs transform the irradiation photons energy into localized SPR oscillations and hot electrons move quickly to other part of nanostructured electrode.<sup>39–42</sup> Higher activity of Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs could be attributed to the photoexcited Ag<sub>2</sub>S semiconductor and plasmon-induced Ag NPs. Moreover, further enhancement of photocatalytic activities was observed after the introduction of GO. No matter what kind of combinations, after covering with GO, the photocatalytic degradation efficiencies were improved by 200–300%. With the combination of GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs, the degradation efficiency of CV reached maximum to 80.01%. Therefore, GO played an important role in the enhanced activity of Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs.

Fig. 5 (a and b) show the comparison of the photocurrent density of different samples with light on/off under simulated solar irradiation. The photocurrent of pure TiO<sub>2</sub> was zero, while the photocurrent density of Ag-TiO<sub>2</sub> NRAs and Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs increased. And Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs raised to about 1.92 mA cm<sup>-2</sup> at 0 V. After composited with GO, the photocurrent of GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs was remarkably improved 10 times to 6.77 mA cm<sup>-2</sup> at 0 V, which indicated that higher efficient separation of photo-generated carriers occurred. At the same condition, dark current density of GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs (4.64 mA cm<sup>-2</sup> at 0 V) was only 68% of that under visible light. Thus reasonable amount of GO in nanostructure could act as a sinker for photoinduced charge carriers, promoting charge separation to enhance the overall photocatalytic efficiency in contact with TiO<sub>2</sub>. The promotion could be contributed to the addition of p-type semiconductor of GO which has hollow sites.<sup>14</sup> In the GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs sample, Ag<sub>2</sub>S and TiO<sub>2</sub> are both n-type,<sup>43</sup> the introduction of GO

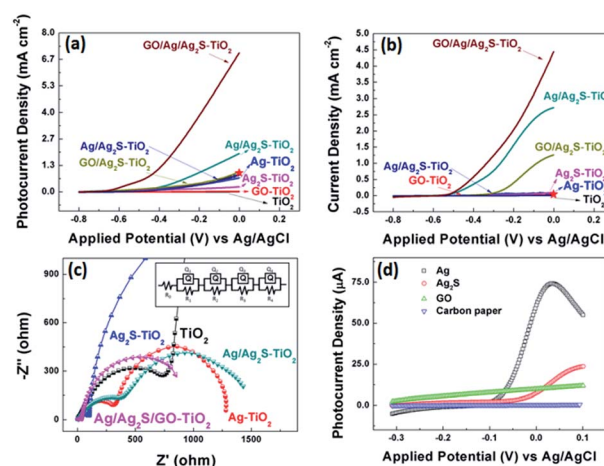

Fig. 5 (a)  $j$ - $V$  characteristics of all samples under visible light illuminations; (b)  $j$ - $V$  characteristics of all samples without light illuminations. The red stars in (a, b) indicate the current density of TiO<sub>2</sub>/rGO/NiFe-LDH NRAs reported by Ning *et al.* under same voltage condition;<sup>36</sup> (c) partial enlarged detail Nyquist plots under visible light at open circuit voltage of all decorated sample and the equivalent circuit for samples; (d)  $j$ - $V$  characteristics for various combination of Ag, Ag<sub>2</sub>S and GO decoration on carbon paper under visible light illuminations.

will compose p-n junction in the sample, then the junction could enhance the current transferring through the electron and hole sites among the composites of the sample. Ning *et al.* have reported a core-shell heterostructure TiO<sub>2</sub>/rGO/NiFe-LDH NRAs which own an enhanced photoconversion efficiency (0.58% at 0.13 V vs. SCE) and photocurrent density (1.74 mA cm<sup>-2</sup> at 0.6 V vs. SCE).<sup>44</sup> For comparison, we plot current value at same voltage as red star on our PEC figures. Moreover, in site doped Au/TiO<sub>2</sub> nanotube photoanode made by Wu,<sup>45</sup> and GO-coated TiO<sub>2</sub> nanoparticles fabricated by Kim *et al.*<sup>46</sup> were all tested by photocurrent. The relative datas were organized in Table 2. Compared with recent results, our material's performance on separation of electrons and holes make a quite big progress.

EIS measurements for all samples were also conducted under visible light irradiation, as shown in Fig. 5(c) as the enlarged image of full spectra (see Fig. S2†). This method can characterize the charge-carrier migration. An equivalent circuit was used to fit the Nyquist plots as shown in the inset of Fig. 5(c) and simulated data were shown in Table S2.† All the hybrid nanostructured samples showed depressed semicircles at high frequencies compared with pure TiO<sub>2</sub> counterparts. The reduced semicircles indicate diminished resistance of working electrodes, suggesting a decrease in the solid state interface layer resistance and the charge transfer resistance across the solid-liquid junction on the surface by forming hybrid structures of decorated TiO<sub>2</sub> NRAs with GO.<sup>47</sup> The  $R_0$  are the

Table 1 Degradation efficiency of CV under 120 min-visible light irradiation

Sample	TiO <sub>2</sub>	GO-TiO <sub>2</sub>	Ag-TiO <sub>2</sub>	GO/Ag-TiO <sub>2</sub>

Degradation efficiency (%)	13.51	31.77	28.92	80.01

Table 2 Comparison of recent work on photocurrent and relative excitement condition

Group/system	Photocurrent (mA cm <sup>-2</sup> )	Voltage (V)	Light resource	Electrolyte
Ning <i>et al.</i> TiO <sub>2</sub> /rGO/NiFe-LDH nanorods	1.74	0.6	150 W Xe lamp	0.5 M Na <sub>2</sub> SO <sub>4</sub> solution
Wu <i>et al.</i> Au/TiO <sub>2</sub> nanotubes	0.50	0	300 W Xe lamp	0.1 M Na <sub>2</sub> SO <sub>4</sub> solution
Kim <i>et al.</i> GO-coated TiO <sub>2</sub> nanoparticles	1.25	0	300 W Xe arc lamp	0.1 M HClO <sub>4</sub> solution
This work	6.98	0	300 W Xe lamp	0.1 M KOH solution

resistance of FTO substrate.  $Q_1$  and  $R_1$  represent the double layer on the reference electrode. The obtained Nyquist spectra show two arcs, the first arc ( $R_2$ ), at higher frequencies, is related to the interfacial resistance between TiO<sub>2</sub> nanorod array and electrolyte. And the arcs at the intermediate frequencies represent the resistance ( $R_3$ ) of holes transferred to the electrolyte through surface states (such as Ag or Ag<sub>2</sub>S NPs) and the capacitance of surface states. For Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs, Ag NPs was deposited after Ag<sub>2</sub>S decoration.

However, based on HRTEM analysis, the Ag and Ag<sub>2</sub>S are separately attached on the TiO<sub>2</sub> arrays surface. So, an extra resistance ( $R_4$ ) was added and can be described as electron or hole transfer between NPs of Ag and Ag<sub>2</sub>S. When layer of GO was coated, the  $R_4$  can also represent the transfer between the decorated TiO<sub>2</sub> and GO. All simulated data are listed in Table S2.†<sup>48</sup> Based on the results, it can be seen that the additions of Ag or/and Ag<sub>2</sub>S can decrease the  $R_2$  and  $R_3$ , implying the reduced transferring resistance between the deposition substrate and TiO<sub>2</sub>. The extra introduction of GO can decrease the hole transfer resistance ( $R_3$ ) dramatically. By comparing the EIS data, GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs are superior to other samples with smaller semicircles, suggesting a rapid transport of charge carriers and an effective charge separation, which is in agreement with the PEC analysis.

In the photocurrent measurements, the obtained currents tested under visible light include photocurrent for oxygen evolution reaction (OER), and electrochemical current caused by applied potential in OER process. So, we use current with light minus the one without light in order to investigate more specific on photo-catalysis progress. Then, the largest current value obtained on GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs was used as reference. The currents of all the other samples were divided by the reference to calculate the relative values, which are listed in Table 3. According to data, it can be easily obtained that simply composing between Ag and Ag<sub>2</sub>S particles doesn't improve the photocatalytic performance so much. Only after the addition of GO layer, the activities of all system enhance remarkably, while the GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs has maximum increment up to 7.7 times. GO layer could both enhanced transmission of charges and protect NPs from corrosion. What's more, to confirm the reaction mechanism and active reaction sites among all the possible composites, we

deposited the single composite on carbon paper rather than TiO<sub>2</sub> NRAs. Then the photocurrents of the prepared samples were recorded under the same test condition which are shown in Fig. 5(d). Basing on the tests, the onset potentials of Ag is most negative among all the prepared samples, implying that Ag has lowest OER overpotential among the four species.

The evolution of the CV solution's absorption spectra for GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs are recorded during the whole reaction process every 30 min time point. From Fig. 6(a), the intensity of peak gradually declines with longer irradiation time which indicates reduced concentration of dye. To analyse the products after reaction, mass spectrometer (MS) for CV in aqueous solution before and after prolonged irradiation (120 min) are also studied, shown in Fig. S3.† As standard CV molecular ( $M = 407.99$ ) concerned, peak at  $m/z = 372.23$  indicate CV molecular which equals to formula weight minus chloridion. When we infer product after reaction from  $m/z = 152.12$ , it is exactly coincident to 1/3 part of whole molecular that three C-C bonds of C atom in central broken up. The result means there is a single product after degradation reaction.

Photoluminescence (PL) technique is an effective way to study the efficiency of the charge carrier trapping, migration and transfer, as PL signals result from the recombination of photo-induced carriers. Fig. 6(b) presents the PL spectra of all test samples. The peaks at ~515 nm can be attributed to the self-trapped excitations and the oxygen vacancies ( $V_o$ ) in TiO<sub>2</sub>.<sup>49,50</sup> Due to the metallic particle decoration on TiO<sub>2</sub>, the PL peaks of TiO<sub>2</sub> become weaker. The PL intensity of GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs is much lower than that of other nanostructures, implying a lower recombination rate of photo-induced electron-hole pairs, and thus a better photocatalytic performance. While PL intensity of Ag-TiO<sub>2</sub> NRAs, Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs and Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs are between TiO<sub>2</sub> NRAs and GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs which is corresponding with dye degradation results.

### Photocatalytic mechanism

Basing on above results, the photocatalytic mechanism of GO/Ag/Ag<sub>2</sub>S-TiO<sub>2</sub> NRAs can be proposed as below. The valence band-edges of materials are shown in Fig. 6(c). In the composite, Ag NPs, Ag<sub>2</sub>S NPs (always n-type) and GO sheets

Table 3 Current density percentage (excluded OER) of all samples at -0.3 V vs. Ag/AgCl

Sample	TiO <sub>2</sub>	GO-TiO <sub>2</sub>	Ag-TiO <sub>2</sub>	GO/Ag-TiO <sub>2</sub>
Percentage (%)	0	0.22	12.89	2.11
Sample	Ag <sub>2</sub> S-TiO <sub>2</sub>	GO/Ag <sub>2</sub> S-TiO <sub>2</sub>	Ag/Ag <sub>2</sub> S-TiO <sub>2</sub>	GO/Ag/Ag <sub>2</sub> S-TiO <sub>2</sub>
Percentage (%)	7.59	16.11	12.97	100.00

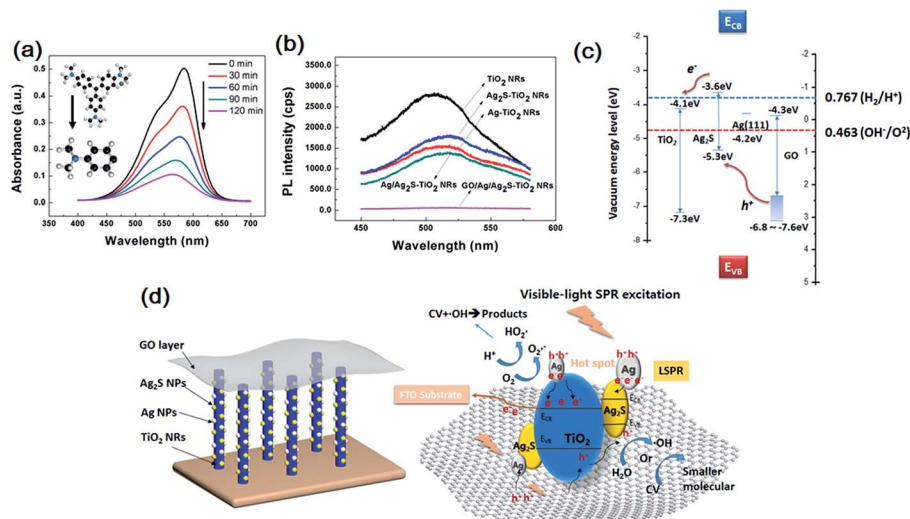

Fig. 6 (a) UV-visible absorption spectra recorded during the catalytic degradation of CV over GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs; (b) photoluminescence (PL) spectrum of single TiO<sub>2</sub> NRAs, Ag–TiO<sub>2</sub> NRAs, Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs, Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs and GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs; (c) band edge positions of TiO<sub>2</sub>, Ag<sub>2</sub>S, Ag and GO; (d) photocatalytic process for GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs under visible light.

(typical p-type) are active to visible light. The higher activity of GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRs could be contributed to the photoexcited.

Ag<sub>2</sub>S semiconductor, plasmon-induced Ag NPs, effective electron–hole separation of GO and clever combination of all the composites. Under visible light irradiation, Ag nanoparticles are photoexcited owing to their SPR effect, and then charge separation is accomplished, where the electrons transfer from Ag nanoparticles to the TiO<sub>2</sub> CB, leading to the generation of holes in Ag nanoparticles for oxidation of OH<sup>•</sup>. Meanwhile, Ag<sub>2</sub>S NPs and GO are also excited to form electrons and holes.<sup>51</sup> Considering that the CB of Ag<sub>2</sub>S is more positive than that of TiO<sub>2</sub>,<sup>52,53</sup> electrons generated from Ag<sub>2</sub>S also tend to transfer into the CB of TiO<sub>2</sub>. This facilitates the separation of electrons and holes. Besides, covering of GO layer remarkably enhances full-wavelength absorption from UV-vis spectra reported in Fig. 4(f), which accomplishes high-usage of visible light. Since work electrode surface is positively charged, excited electrons from GO are easier to move into TiO<sub>2</sub>. Then, vast holes tend to move directly into Ag NPs which consume holes quickly because of its lowest OER overpotential among the four species in the composite, resulting acceleration of the whole reaction. Thus Ag NPs is probably active OER reaction sites for the whole system. Ag nanoparticles also act as the charge transmission bridges, which can efficiently promote the separation of electron–hole pairs. Also, both Ag and Ag<sub>2</sub>S combination with TiO<sub>2</sub> could narrow down its original band gap, it may enhance the adsorption efficiency of the composite.

Then electrons can either reduce the dye or can react with electron acceptors (O<sub>2</sub> absorbed on the surface of Ti<sup>3+</sup> or dissolved in water) to create superoxide radicals (O<sub>2</sub><sup>•-</sup>). Meanwhile, the resultant electron-deficient Ag particles can oxidize the organic molecule or react with OH<sup>-</sup> to form hydroxyl radicals, OH<sup>•</sup>. The process is demonstrated in Fig. 6(d). The co-decoration of Ag/Ag<sub>2</sub>S NPs and GO not only extends TiO<sub>2</sub> to visible light region, but also increases the efficiency of charge separation and improves its photocatalytic efficiency.

## Conclusions

In summary, we obtained the procedure for preparation of the TiO<sub>2</sub> NRAs on various substrates including FTO, Si and *et al.*, and fabricated successfully GO/Ag/Ag<sub>2</sub>S–TiO<sub>2</sub> NRAs by using SILAR technique and impregnation method. By comparing with TiO<sub>2</sub> NRAs, it exhibits remarkable improvement of photocatalytic activity for dye degradation and PEC performance. The enhanced photocatalytic activities through decoration of the NRAs are attributed to the synergy of matched band of Ag<sub>2</sub>S NPs, SPR effect of Ag NPs and rapid transport of charge carriers that improves charge separation of system. Our studies demonstrate that we can utilize photon in a wider range of solar spectrum to generate charge carriers for photocatalytic reactions through rational design of composite nanostructures. The combination of GO with traditional photocatalyst also provides a more effective way to harvest solar energy for decomposition reaction.
