Facile preparation of a tetraethylene pentamine-functionalized nano magnetic composite material and its adsorption mechanism to anions: competition or cooperation†

Meiqin Hu, Haoyu Shen, Si Ye, Yan Wang, Jiali Zhang and Shanshan Lv

A tetraethylene pentamine (TEPA)-functionalized nano-Fe₃O₄ magnetic composite material (nFe₃O₄@TEPA) was synthesized by a facile one-pot solvothermal method. It was characterized by elementary analysis (EA), powder X-ray diffraction (XRD), Fourier transform infrared spectrometry (FTIR), transmission electron microscopy (TEM) and vibrating sample magnetometry (VSM). The results show that the nFe₃O₄@TEPA has an average size of ~20 nm, with a saturation magnetization intensity of 48.2 emu g⁻¹. Its adsorption properties were investigated by adsorbing fluoride ions, phosphate, Cr(VI) and their co-existing water system. The adsorption performance was studied as a function of solution pH, initial concentration of ions, contact time and temperature for each ion. The adsorption of the multi-ion co-existing system was studied via batch tests, XPS and FTIR analyses. The effect of co-existing ions was studied through Box-Behnken Design (BBD) and response surface methodology (RSM). It can be deducted that the adsorption mechanism of an individual fluoride ion or phosphate was mainly related to electrostatic attraction, while that of Cr(VI) might be mainly related to electrostatic attraction and coordination interactions. For the fluoride ion and phosphate bi-component system, their adsorption was competitive via ion exchange. For the Cr(VI), fluoride ion and phosphate tri-component co-existing system, Cr(VI) took priority for adsorption and could replace the absorbed fluoride ion or phosphate by competitive reaction, but not vice versa.

1 Introduction

Elevated levels of oxyanions (e.g. arsenite, arsenate, chromate, phosphate, selenite, selenate, borate, nitrate, etc.) and monoa-toxic anions (e.g. fluoride, chloride, bromide, and iodide) have been found in the environment and they can be harmful to both humans and wildlife.¹⁻³ Some of these anions have become the most frequently detected in ground water at hazardous waste sites and have been placed on the top of the priority list of toxic pollutants by the U. S. EPA.⁴ Treatment of anion-containing wastewater prior to discharge is essential. Conventional techniques, such as reduction, reverse osmosis, electrodialysis, ion exchange, and adsorption, have been used for removing these anions from wastewater.⁵⁻⁶ However, the reduction followed by precipitation has some disadvantages, i.e., higher waste treatment equipment costs, significantly higher consumption of reagents, and significantly higher volume of sludge generated.⁷ Although reverse osmosis and electrodialysis are superior in recovering some of the oxyanions, such as Cr(VI), it is difficult to reduce the oxyanions in the effluent to an acceptable level.⁸ As far as ion exchange is concerned, it is an attractive approach in treating the wastewater containing anions, but ion exchange system is the complexity in regenerating the resin.⁹ Recently, Fe₃O₄-based magnetic nanoparticles (MNPs) have found to be simple, convenient, and powerful approaches for the separation and purification of environmental samples, and removal of toxic pollutants, including various ions, in water.⁵⁻¹⁰ However, most reports are focused on the treatment of one-ion component solution. Those for co-existing solutions, especially for adsorption mechanism investigating are quite limited.⁵⁻¹⁰ The industrial effluents often contain several kinds of oxyanions and monoatomic anions, the study of which is very complicated because of their synergistic, antagonistic or non-interactive effects on their adsorption. The traditional one-factor-at-a-time approach to run and analyze the experiments cannot successfully predict possible interactions between the oxyanions and monoatomic anions in industrial wastewater. Thus, it is necessary to investigate the simultaneous removal process in multi-component system containing oxyanions and monoatomic anions.

Multivariate analysis allows significant reduction in the number of experiments in addition to the description of independent variables impact on the process. This can contribute to
the development and optimization of the multi-component system while it significantly decreases the cost of experiments. Response surface methodology (RSM) is one of the most popular methods applied in research on adsorption processes.\textsuperscript{16,17} The RSM is a useful statistical tool used to design experiments in which factors and their levels are determined. After handling the response of the experiments, the results are obtained by analyzing the response according to the RSM. A mathematical model is set via RSM by considering both linear and nonlinear relationships between independent variables, namely factors and response. If interactions affect the response, it can be mathematically modeled which allows for the optimization of the response. Based on such model, response surface graph and contours are provided, which help to visualize the shape of response surface.\textsuperscript{18,19} Thus, simultaneous modeling and optimization of variables are required to achieve an economic and popular wastewater treatment.

In this work, a tetraethylenepentamine (TEPA)-functionalized nano-$\text{Fe}_3\text{O}_4$ magnetic composite materials ($\text{nFe}_3\text{O}_4@\text{TEPA}$) was synthesized by a facile one-pot solvothermal method. It was characterized by elementary analysis (EA), powder X-ray diffraction (XRD), Fourier transform infrared spectrometer (FTIR), transmission electron microscopy (TEM), dynamic light scattering (DLS) and vibrating sample magnetometer (VSM).

The objective of this study is to investigate its adsorption properties of fluorine ion, phosphate, Cr$\text{(VI)}$ and their co-existing water system. On the basis of the adsorption performance investigating of single-component for each ion, the adsorption of multi-component of the co-existing system was statistically studied. Presumed mechanisms were deeply investigated based on batch tests, thermodynamic and kinetic studies, XPS and FTIR characterization and RSM analyses. The overall procedure of the present work was shown in Scheme 1.

## 2 Experimental

### 2.1 Materials

Ferric chloride ($\text{FeCl}_3\cdot\text{6H}_2\text{O}$), sodium acetate (NaAc), ethylene glycol (EG), potassium fluoride (KF), potassium dihydrogen phosphate ($\text{KH}_2\text{PO}_4$), potassium dichromate ($\text{K}_2\text{Cr}_2\text{O}_7$) were analytical grade, and purchased from Sinopharm Chemical Reagent Co., Ltd. Tetraethylenepentamine (TEPA) was supplied by Aladdin Chemical Reagent Co., Ltd. (Shanghai, China). Distilled water was used to prepare all the solutions. 0.5 mol L$^{-1}$ HNO$_3$ and 0.5 mol L$^{-1}$ NaOH solutions were used for pH adjustment.

### 2.2 Preparation of $\text{nFe}_3\text{O}_4@\text{TEPA}$

The overall preparation of $\text{nFe}_3\text{O}_4@\text{TEPA}$ was produced using a polyol-media one-pot solvothermal method. 4.0 g of FeCl$_3\cdot\text{6H}_2\text{O}$ and 12.0 g of NaAc were dissolved in 120 mL ethylene glycol. This solution was stirred vigorously at room temperature for 10 min to form a stable orange solution. 40 mL of TEPA was then added with constant stirring for 30 min until completely dissolved. The mixture solution was then transferred to an autoclave and heated to 180°C for 6 h. The product was then isolated by a magnet and dried in vacuum.

Scheme 1: Overall procedure of the $\text{nFe}_3\text{O}_4@\text{TEPA}$ facile preparation and its adsorption to anions.
a Teflon-lined autoclave and heated at 180 °C for 8 h. After the autoclave cooled to room temperature, the resulting nFe3O4@TEPA was isolated under magnetic field and washed with water and ethanol to remove redundant reagents and impurities. The as-prepared nFe3O4@TEPA was dried in a vacuum oven at 60 °C for 12 h and stored in a sealed bottle for further use.

2.3 Characterization

Transmission electron microscopy (TEM) images were obtained on a JEM-2100F Lorentz-Transmission Electron Microscopy (TEM) at an accelerating voltage of 200 kV. The magnetic properties of magnetic particles were measured using a vibrating sample magnetometer (VSM, Lake Shore 7410). Powder X-ray diffraction (XRD) patterns were collected on an X-ray diffractometer (Bruker D8 Advance) with CuKα radiation at λ = 0.154 nm operating at 40 kV and 40 mA. The elementary analysis results of the nitrogen contents in nFe3O4@TEPA were measured using an elementary analysis (EA, Thermo Fisher Flash-1112). Fourier Transform Infrared spectrometer (FTIR, Thermo Nicolet, USA) and X-ray photoelectron spectroscopy (XPS, AXIS ULTRADLD) were used to investigate the adsorption mechanism. Dynamic light scattering (DLS, Nano ZS-90) was used to determine the mean particle size.

The content of Fe3O4 in nFe3O4@TEPA was calculated from the amount of leached Fe, which was measured using a spectrophotometer (722, Shanghai, China) according to the standard colorimetric method21 after digesting nFe3O4@TEPA in 12 mol L−1 HCl solution. The concentration of fluoride ion (F−), phosphate or Cr(vi) in the aqueous solution was analyzed following the standard methods for examination of water and wastewater.22 Briefly, the concentration of fluoride ion was carried out using combined fluoride-specific ion-selective electrode carried out using combined fluoride-specific ion-selective electrode on a SevenMulti™ instrument (Mettler Toledo). The concentration of phosphate was analyzed spectrophoto metrically by the molybdenum blue method at 690 nm by adding [NH4]2MoO4 and SnCl2–HCl solutions followed by being kept in the dark for 10 min at room temperature (722, Shanghai, China). The concentration of Cr(vi) ions in the aqueous solution was analyzed with a spectrophotometer at a wavelength of 540 nm after acidification of samples with 1 N H2SO4 and reaction with 1,5-diphenyl carbazide to produce a purple color complex for colorimetric measurement (722, Shanghai, China).

2.4 Adsorption experiments

A stock solution of fluoride ion (F−), phosphate or Cr(vi) at concentration of 1000 mg L−1 was prepared by dissolving a known quantity of potassium fluoride (KF), potassium dihydrogen phosphate (KH2PO4) or potassium dichromate (K2Cr2O7) in ultrapure water. Batch adsorption experiments were carried out in 150 mL stoppered flasks, each of which contained 25.00 mL of fluoride ion (F−), phosphate or Cr(vi) individual solutions or co-existing solutions of varying concentration, from 10 to 1000 mg L−1. A 0.02 g amount of nFe3O4@TEPA was added into each flask and shaken at 150 rpm in a thermostatic shaker. 0.5 mol L−1 HNO3 and 0.5 mol L−1 NaOH solutions were used for pH adjustment, ranging from 2.0 to 10.0. Adsorption kinetic and thermodynamic studies at different temperatures (25–45 °C), with contacting time ranging from 1 to 180 min, were also carried out. Effect of co-existing ions was studied through Box-Behnken Design (BBD) and the response surface methodology (RSM). The post-adsorption solutions were separated magnetically under a NdFeB magnet.

According to the concentrations before and after adsorption, the equilibrium adsorption capacity (qe, mg g−1) of the studied anions absorbed to the nFe3O4@TEPA is calculated using eqn (1):21

\[
q_e = \frac{(C_0 - C_e)V}{m}
\]

where \(C_0\) and \(C_e\) represent the initial solution concentration and the equilibrium concentration of fluoride ion (F−), phosphate or Cr(vi) (mg L−1), \(V\) is the volume of the solution (mL), \(m\) is the adsorbent dosage (mg), the same hereinafter.

For the kinetic studies, the pseudo-first-order model (eqn (2)),21 pseudo-second-order model (eqn (3)),21,22 and intraparticle diffusion model (eqn (4)),21 were used to fit the experimental data.

\[
\log(q_e - q_t) = \log q_e - \left(\frac{k_1}{2.303}\right)t
\]

\[
\frac{t}{q_t} = \frac{1}{k_2q_e^2} + \left(\frac{1}{q_e}\right)t
\]

\[
q_t = k_{id}t^{1/2} + C
\]

where, \(q_e\) and \(q_t\) are the adsorption capacities at equilibrium and at time \(t\) (mg g−1), respectively. \(k_1\) (min−1), \(k_2\) (g (mg−1 min−1)) are the adsorption rate constants, \(k_{id}\) is the intraparticle diffusion rate constant (mg g−1 min−1/2), \(C\) is the intercept (mg g−1).

For the adsortion isotherm studies, two adsorption isotherms, Langmuir model (eqn (5))21,22 and Freundlich model (eqn (6)) were applied to analyze the adsorption data.21,24

\[
\frac{C_e}{q_e} = \frac{1}{K_L q_m} + \frac{C}{q_m}
\]

\[
\log q_e = \log K_F + (1/n)\log C_e
\]

where, \(q_m\) and \(K_L\) are the Langmuir constants related to the maximum adsorption capacity and apparent heat change, respectively, while \(K_F\) is a Freundlich constant related to the adsorption intensity.

3 Results and discussion

3.1 Characterization of nFe3O4@TEPA

The TEM images of nFe3O4@TEPA were shown in Fig. 1(a). All the size data reflect the averages of about 100 particles and are calculated according to eqn (7).23
\[ U = D_n / D_w, \quad D_n = \frac{\sum n_i D_i}{\sum n_i}, \quad D_w = \frac{\sum n_i D_i^4}{\sum n_i D_i^2} \] (7)

where \( U \) is the polydispersity index, \( D_n \) is the number-average diameter, \( D_w \) is the weight-average diameter, and \( D_i \) is the diameter of the determined microspheres. It revealed that the nFe₃O₄@TEPA particles were multidispersed with some aggregation at an average diameter of around 20 nm (Fig. 1(a)), with \( D_n \) at 21.5, \( D_w \) at 22.8, and \( U \) at 1.06. In order to check the aggregation behavior, we carried out the DLS experiments of nFe₃O₄@TEPA from 0–10 min. As shown in Fig. 1(b), the particles aggregated gradually and the intensity average diameter measured by DLS increased from 25 nm to 40 nm after 1 minute, and 75 nm after 10 minutes. This might be due to the dipolar magnetic interaction between the magnetic cores and hydrogen bonds between the amino groups on the surface of the magnetic cores.

The FTIR spectra of nFe₃O₄ and nFe₃O₄@TEPA were showed in Fig. 2(a). Characteristic band of nFe₃O₄ occurs at ~589 cm⁻¹. Other typical bands can be assigned as follows, \( \nu(-\text{OH}) \): ~3446 cm⁻¹, \( \nu(-\text{CH}_2) \): ~2924 cm⁻¹, ~2853 cm⁻¹, \( \delta(-\text{CH}_2) \): ~1429 cm⁻¹ for PEG. Compared with nFe₃O₄, after functionalization by TEPA, typical bands at ~1573 cm⁻¹ can be assigned to be the stretching and bending vibrations of the \(-\text{NH}\) and \(-\text{NH}_2\) groups appeared, with a great shift of the bands for \( \delta(-\text{CH}_2) \). This revealed that the amino groups of TEPA had been successfully grafted to the surface of the nFe₃O₄. The superparamagnetic properties of the nFe₃O₄@TEPA were verified by
the magnetization curve measured by VSM, shown in Fig. 2(b). The saturation moment obtained from the hysteresis loop was found to be 48.2 emu g\(^{-1}\). The nFe\(_3\)O\(_4\)@TEPA was expected to respond well to magnetic fields without any permanent magnetization, therefore making the solid and liquid phases separate easily. Due to the anti-magnetic property of the TEPA, it was no surprise the saturation moment of nFe\(_3\)O\(_4\)@TEPA lower than that of the naked nano-Fe\(_3\)O\(_4\) (78.6 emu g\(^{-1}\), as shown in Fig. 2(b)). Interestingly, the saturation moment of the present nFe\(_3\)O\(_4\)@TEPA was much higher than those of our previously reported nano magnetic polymers (NMPs), which was ranged from 12.3 to 5.56 emu g\(^{-1}\),\(^{29}\) which might be due to two facts: (1) anti-magnetic polymer anchored onto the Fe\(_3\)O\(_4\) core of the NMPs, which leading a decrease of content percentage of Fe\(_3\)O\(_4\) in the NMPs; (2) by using solvothermal method, amino-groups of TEPA self-assembled graft to the surface of the magnetic cores via hydrogen bonds between the amino groups and active hydroxyl groups of Fe\(_3\)O\(_4\). The obtained nFe\(_3\)O\(_4\)@TEPA with good dispersity to avoid the dispersion agglomeration defects in the traditional preparation process. With a large number of amino groups on the surface of the nFe\(_3\)O\(_4\), it is beneficial to form magnetic ordered structure, which leading an increase of the saturation moment. This phenomenon was also found by Yoon, et al.\(^{27}\) High saturation magnetization (56.1 emu g\(^{-1}\)) of the Fe\(_3\)O\(_4\) based magnetic polymer composite material-Fe\(_3\)O\(_4\)@DAPF was found when solvothermal method was used for preparation. To further demonstrate the crystal structure of nFe\(_3\)O\(_4\)@TEPA, the XRD patterns of the as-prepared Fe\(_3\)O\(_4\) (without adding TEPA) and nFe\(_3\)O\(_4\)@TEPA were collected (Fig. 2(c)). It indicated that nFe\(_3\)O\(_4\)@TEPA had retained the spinel structure of Fe\(_3\)O\(_4\), in which the identical peaks for Fe\(_3\)O\(_4\) located at 30.1, 35.5, 43.1, 53.4, 57.0 and 62.6, corresponding to their indices (220), (311), (400), (422), (511) and (400) appeared.\(^{28}\)

Elemental analysis results showed that nitrogen percentage of nFe\(_3\)O\(_4\)@TEPA was 18.9%, while the total content of Fe\(_3\)O\(_4\) in the nFe\(_3\)O\(_4\)@TEPA was 58.2%, which was higher than those of our previously reported NMPs, and consisted with the VSM results.

3.2 Adsorption mechanism of the nFe\(_3\)O\(_4\)@TEPA to anions

3.2.1 Effect of pH and adsorption mechanism for the individual ion. The pH effect of fluoride ion (F\(^-\)), phosphate or Cr(vi) individual solutions at concentration of 50 mg L\(^{-1}\) of nFe\(_3\)O\(_4\) (a) and nFe\(_3\)O\(_4\)@TEPA (b).
Under acidic conditions (pH at 2.0–3.5), amino groups were easier to be protonated (–NH₃⁺), as described by eqn (12). Electrostatic attraction happened as in eqn (13), leading a decrease of the residue concentration of Cr(vi). With increasing of the pH value, the concentration of H⁺ was decreased, and at the same time the concentration of OH⁻, which competed with HCrO₄⁻, was increased. So the ability of –NH₂ to be protonated was weakened, resulting in the decline of removal efficiency.

With the increasing of pH value, an interesting phenomenon was observed that there was a flat, as we found before in amino-functionalized nano magnetic polymers (NMPs). This implied that besides the electrostatic attraction and ion exchange interactions, coordination interactions might occur in the adsorption process. as in eqn (14).

In the case of phosphate, as shown in Fig. 3(c), the percentage of uptake phosphate for nFe₃O₄@TEPA increased from 31.9% to 81.4% sharply to a maximum at pH 3.0, then decreased sharply to 26.0% at pH 6.0. As shown in Fig. 4(b), phosphate existed in the forms of H₃PO₄, H₂PO₄⁻, HPO₄²⁻ and PO₄³⁻, depending on the solution pH (pK₁ = 2.15, pK₂ = 7.20, and pK₃ = 12.33). With an increase of pH, the nFe₃O₄@TEPA surface carried positive charge, and thus would more significantly attract the negatively charged monovalent H₂PO₄⁻ ions in solution, which indicated that the physicochemical adsorption due to electrostatic attraction was the predominant process of phosphate removal, as described by eqn (15). When the pH of the solution increased, the surface became negatively charged, consequently, unfavorable to the phosphate for electrostatic repulsion.
In the case of fluoride, as shown in Fig. 3(d), unlike Cr(Ⅵ) and phosphate, the adsorption capacity was almost not dependent on solution pH. To our knowledge, this is one of the longest pH ranges of the materials for F− adsorption in literature. The percentage of uptake fluoride for nFe3O4@TEPA kept constant at around 95.6% under pH value from 2.0 to 11.0, and gradually decreased to 70.2% at pH 14. Such high fluoride removal efficiencies are much better than those in prior reports. For instance, Kong et al. reported the fluoride removal efficiency of MHS-MgO/MgCO3 adsorbent was 86.2%, 83.2% and 76.5% at pH = 11 for initial fluoride concentrations of 10, 20 and 30 mg L−1, respectively.36 Mohapatra et al. studied the fluoride removal efficiency of Mg-doped nano Fe3O4 adsorbent was almost 30% at pH = 11 initial fluoride concentration 10 mg L−1.37 Swain et al. demonstrated that the fluoride removal efficiency of Fe(m)-Zr(Ⅳ) binary mixed oxide was about 38% at pH = 11.38 As shown in Fig. 4(c), fluoride mainly existed in the forms of HF, F−, depending on the solution pH (pK = 3.18). Although, some literatures39-41 showed that in the acidic pH range (pH < 5), weak hydrofluoric acid (HF) is present in the experiments may affect defluoridation, no obvious decrease of the uptake fluoride was observed in this work. Thus, we assume that besides electrostatic attraction, hydrogen bonds might form in the process of fluoride removal, as described by eqn (16)−(18). In the strongly alkaline range (pH > 11), there is a drop at around 25% in adsorption percentage, which may be due to the competition of hydroxyl ions with the fluoride and the electrostatic repulsion from the surface of nFe3O4@TEPA.

nFe3O4@TEPA showed that all the three kinds of anions, the adsorption capacity increased rapidly and reached equilibrium in 10 min and intra-particle process might not be involved in the rate-limiting steps. The adsorption kinetic experimental data fit the pseudo-second-order model well for all the studied anions. The activation energies of the adsorption process, Ea, are found to be 19.56 kJ mol−1, 23.71 kJ mol−1, 25.35 kJ mol−1 for fluoride ion (F−), phosphate or Cr(Ⅵ), respectively. All are less than 42 kJ mol−1, indicating that diffusion process was the rate-controlled step.40 Detailed discussions were presented in ESI, S1 Kinetic studies and Fig. S1, Table S1 and S2.†

3.2.3 Adsorption capacity of nFe3O4@TEPA to anions. The adsorption capacities of nFe3O4@TEPA to fluoride ion (F−), phosphate or Cr(Ⅵ) mono-component were investigated. Detailed discussions were presented in ESI, S2 Adsorption capacity and Fig. S2, Table S3 and S4.† The results showed that the Langmuir models fit the data well, suggesting a monolayer adsorption. The maximum adsorption capacities (qm) for fluoride ion (F−), phosphate or Cr(Ⅵ) are 163.9, 149.3, and 400 mg L−1, respectively. Interestingly, although the adsorption to all the studied anions the nFe3O4@TEPA was spontaneous in nature (∆G < 0), the enthalpy changes (∆H°) for the fluoride ion (F−), phosphate or Cr(Ⅵ) were found to be at 38.54, 13.89, 88.03 kJ mol−1 (Table S4†), respectively, which indicated that the adsorption was endothermic. For physical adsorption, the process of adsorption is usually exothermic, that is, the increase of temperature is not favorable to the adsorption. However, chemisorption is some of endothermic, and some of exothermic. In general, it is thought that the increase in temperature is beneficial to chemisorption.42 Similar results were found in our previous work13,17 and in literature.43

3.2.4 Effect of co-existing ions and presumed mechanism. The effect of co-existing ions experimental studies were investigated with a standard response surface methodology (RSM) design called Box-Behnken Design (BBD). RSM is a useful mathematical and statistical technique for the development of empirical relation between the experimental outputs (responses) and process parameters (factors). A well designed RSM approach leads to optimize the process parameters for improving the responses. The experimental parameters (Xi (initial concentration of Cr(Ⅵ), C(Cr(Ⅵ))), X2 (initial concentration of fluoride ion (F−), C(F)), and X3 (initial concentration of phosphate, C(P)), for design of experiment strategy are considered at three levels and coded as −1, 0, and +1 for low, middle and high level respectively. The coded and actual values of the independent variables and predicted response of the model were shown in Table S5 and S6.† In the BBD modeling of three factors and three levels, the center point was repeated for five times in order to improve the accuracy in estimation of errors. The response of the model was analyzed by analysis of variance (ANOVA) and a second-order polynomial model (as shown in eqn (19)) was fitted to correlate between the independent variables (X1, X2 and X3) and the response for anions removal in order to predict the of co-existing ions effect.

\[
Y = K_0 + \sum_{i=1}^{n} K_i X_i + \sum_{i=1}^{n} K_{ij} X_i^2 + \sum_{1 \leq i < j \leq n} K_{ij} X_i X_j + \varepsilon \tag{19}
\]
where $Y$ represents the predicted response variables $i.e.$ the amount of anions adsorbed by nFe$_3$O$_4$@TEPA, $K_0$ is the constant coefficient, $K_i$ is the linear coefficient of the input factor $X_i$, $K_{ii}$ is the $i$th quadratic coefficient of the input factors $X_i$, $K_{ij}$ is the different interaction coefficients between input factors $X_i$ and $X_j$, and $\epsilon$ is the error of the model. The software Design Expert (Version 8.0.6.1) was used for model statistic, like experimental design, determination of the coefficients, data analysis and the graph plotting.

The adsorption capacities of nFe$_3$O$_4$@TEPA to fluoride ion (F$^-$), phosphate or Cr(VI) multi-component solution was carried out by means of BBD of RSM. Quadratic model were used to know the adsorption capacity of the fluoride ion (F$^-$), phosphate or Cr(VI), respectively, shown in ESI eqn (S6)–(S8). The positive sign and the negative sign of the term indicates the synergetic and antagonistic effect respectively. The ANOVA data shown in Table S7–S9 of ESI† for Response 1 ($q$(Cr)), Response 2 ($q$(F)), and Response 2 ($q$(P)), respectively. The coefficient of determination ($R^2$), which measure the degree of fit in the model was found to be 0.9956, 0.9923, 0.9920 and an Adj-$R^2$ of 0.9900, 0.9824, 0.9817, respectively. In addition, the model is very significant as evident from its $F$-value and very low probability $p$-value. If the $p$-value is less than 0.05, it indicates that the model is statistically significant whereas a value higher than 0.05 suggests that the model is not significant.$^{45,46}$ Here, the $F$-values were found to be 177.03, 100.01, 96.19, respectively, and $p$-value were all < 0.0001 for the model.

Values of “Prob > F” less than 0.0500 indicate model terms are significant. As shown in the ANOVA data in Table S7–S9, for the adsorption of Cr(VI), the linear terms, $C$(Cr(VI)) and $C$(P) are significant; while for adsorption of fluoride ion (F$^-$), besides the linear terms, $C$(F), and $C$(P), quadratic terms of $C$(F), and one cross-product coefficients $C$(Cr(VI))$C$(F) and $C$(F)$C$(P) are significant; for adsorption of phosphate, except the one cross-product coefficients $C$(F)$C$(P) is not significant, all the other model terms are significant.

In response surface plots, the adsorption of anions can be better explained by the interaction of all the three factors. The three dimensional plots and contour plots were used to know the effect of two parameters in their experimental range for the removal of anions while the third parameter remains at zero level. From the shape of contour plot, one could be able to explain the nature and extents of interaction between the experimental factors, $i.e.$, the effects of the co-existing ions in the present work. Circular and elliptical shape of contour plots shows the significant interaction between the experimental factors in the model. Therefore maximum adsorption capacity can be explain on the basics of these experimental factors, $i.e.$, the effects of the co-existing ions, here. The effect of the co-existing fluoride ion (F$^-$) and phosphate to the adsorption of Cr(VI) was shown in Fig. 5(a), while the effect of the co-existing Cr(VI) and phosphate to the adsorption of fluoride ion was shown in Fig. 5(b) and the effect of the co-existing Cr(VI) and fluoride ion to the adsorption of phosphate was shown in Fig. 5(c), respectively. Those of the bi-component systems were shown in the Fig. S3 in the ESI.$^\dag$ As shown in Fig. 5, for the tri-component co-existing system, either fluoride ion or phosphate, had little effect on the adsorption competition to Cr(VI). Cr(VI) took priority for adsorption and could replace the absorbed fluoride ion or phosphate by competitive reaction. As shown in Fig. S3, for the fluoride ion and phosphate bi-component system, the adsorption of them was competitive via ion exchange.

The adsorption mechanism could be confirmed by XPS and FTIR analyses of nFe$_3$O$_4$@TEPA before and after adsorption of the studied anions. The survey scan of XPS spectra of Fig. 5 The effect of the co-existing fluoride ion and phosphate to the adsorption of Cr(VI) (a), the co-existing Cr(VI) and phosphate to the adsorption of fluoride ion (b), the co-existing Cr(VI) and fluoride ion to the adsorption of phosphate (c).
nFe₃O₄@TEPA before (a) and after adsorption of phosphate (b) Cr(Ⅵ) (c), fluoride ion (d) and the co-existing the three anions (e) were shown in Fig. 6. From the survey scan of XPS spectra (Fig. 6), new peaks owing to P2p, Cr2p and F1s appeared after adsorption of phosphate (b), after adsorption of Cr(Ⅵ) (c), after adsorption of fluoride ion (d) and after adsorption of the co-existing the three anions (e), suggesting that the phosphate, Cr(Ⅵ) and fluoride ion were successfully adsorbed on the surface of nFe₃O₄@TEPA. High-resolution XPS spectra of nFe₃O₄@TEPA after adsorption of the co-existing the three anions were shown in Fig. S4.† As shown in Fig. S4(a),† the characteristic peaks for Cr(Ⅵ) (Cr2p 1/2, 587.5 eV; Cr2p 3/2, 579.4 eV) appeared, no obvious peaks assigned to Cr(III), normally appeared at Cr2p 1/2, 586.3 eV; Cr2p 3/2, 577.1 eV, were observed, which implied that the main species existed in the surface of the nFe₃O₄@TEPA was Cr(Ⅵ), reduction to Cr(III) hardly occurred, differing from our previous founding.† The characteristic peaks for phosphate (P2p, 113.0 eV) and fluoride (F1s, 685.2 eV) can be found in Fig. S4(b) and (c),† respectively, which clearly confirmed the successful adsorption of phosphate and fluoride.† As shown in Fig. S4(d),† after adsorption, the peaks of NIs appeared at 398.8 eV with a broader band range, which could be attributed to protonated amine groups (–NH₃⁺) and the further formation of –NH₂⁺-anions.† Similar phenomena were observed in the XPS spectra of O1s (Fig. 4(e)), peaks of O1s appeared at ~531.1 eV and ~529.5 eV, assigned to C–O–C and C–OH groups, broadening with a slight shift of binding energies. In the XPS spectra of C1s (Fig. 4(f)), the carbon atoms can be found in two chemically different positions, leading to two differing C1s binding energies: C–O–C (~282.6 eV) and C–O–C (~284.0 eV) or C–OH (~286.5 eV). Changes in atomic concentration of the key elements after the adsorption were summarized in Table S10.† The main elements of the nFe₃O₄@TEPA were Fe, O, N and C. Compared with the initial pre-adsorbed material, the chromium, phosphate, and fluoride atomic percent of the sample was 1.88%, 1.01% and 0.91% after adsorption experiment. It confirmed that the studied anions were undoubtedly adsorbed onto the surface of nFe₃O₄@TEPA.

The FTIR spectra of nFe₃O₄@TEPA before (a) and after adsorption of phosphate (b), Cr(Ⅵ) (c), fluoride ion (d) and the co-existing the three anions (e) were showed in Fig. 7. In Fig. 7(a), the broad peak appeared at ~3360 cm⁻¹ and ~1573 cm⁻¹ can be assigned to be the stretching and bending vibrations of the –NH and –NH₂ groups. While after adsorption, in Fig. 7(b)–(e) the characteristic bands at ~1573 cm⁻¹ disappeared along with the appearance of the bands at ~1630 cm⁻¹, which may be attributed to the interaction between amino groups and the phosphate, Cr(Ⅵ) and fluoride groups, subsequently weakened the N–H bonding and resulted in a large shift (~80 cm⁻¹). The characteristic peaks of Cr(Ⅵ) at ~940 cm⁻¹ and ~760 cm⁻¹ can be observed in the absorption of HCrO₄⁻ and the typical peak at ~540 cm⁻¹ for the “Cr–N” also appeared as shown in Fig. 7(b) and (e). The characteristic peaks of the phosphate groups at 543 cm⁻¹ were also observed in Fig. 7(c) and (e), corresponding to the –PO and –O–P–O groups, respectively.

### 3.2.5 Reusability investigation

The reusable of the nFe₃O₄@TEPA was evaluated by comparing the average adsorption efficiency of a mixture solution of fluoride ion (F⁻), phosphate and Cr(Ⅵ) at each concentration at 20 mg L⁻¹. The post-aborbed nFe₃O₄@TEPA was extracted with 1% NaOH methanol solution for 30 min, and for another adsorption to get the next adsorption efficiency. The results were shown in Fig. 8, indicating that nFe₃O₄@TEPA could be used for at least 10 cycles with a loss of less than 2.8% upon recovery on average. No obvious decrease in the adsorption capacity efficiency was found. The VSM experiments of the recycled nFe₃O₄@TEPA
were tested. The saturation moments obtained from the hysteresis loops were found to be 48.0–47.6 emu g$^{-1}$ from 1 cycle to 10 cycles, (as shown in Fig. 8 (insert)). Compared with the saturation moment of the fresh-prepared nFe$_3$O$_4$@TEPA (48.2 emu g$^{-1}$), which implied that no obvious decrease reduction of the magnetic strength was found.

4 Conclusion
A tetraethylenepentamine (TEPA)-functionalized nano-Fe$_3$O$_4$ magnetic composite materials (nFe$_3$O$_4$@TEPA) was synthesized by a facile one-pot solvothermal method. The as-prepared nFe$_3$O$_4$@TEPA exhibited a homogeneous morphology, strong affinity ability, and high magnetic responsiveness for the adsorption of ions. The adsorption of the multi-ion co-existing system was studied via batch tests, XPS and FTIR analyses, and analyzed via response surface methodology (RSM). The adsorption mechanism of multi-ion component system was intensively studied.
