Determination of the Lewis acidity of amide–AlCl₃ based ionic liquid analogues by combined in situ IR titration and NMR methods

Pengcheng Hu, Wei Jiang, Lijuan Zhong and Shu-Feng Zhou

Acidic amide–AlCl₃ based ionic liquid (IL) analogues have attracted significant attention as good alternatives to traditional imidazolium and pyridinium based halometallate ILs due to their broad acidity-adjusting range, high catalytic activity, low toxicity and cost, and easy preparation.⁴⁻⁶ Amide–AlCl₃ based IL analogues exhibit a mixture of neutral molecular Al species, and cationic and anionic Al species in equilibrium, which contribute to the incomplete asymmetric splitting of Al₂Cl₆ under the induction of amide.⁶⁻⁵ Therefore, multiple Lewis acidic species with catalytic activity exist in these ILs analogues.⁶ The Lewis acidity of the amide–AlCl₃ based IL analogues, including acidic strength and amount, is correlated with their catalytic activity and selectivity.⁷⁻⁹ Hence, it is necessary to establish a suitable method to determine the acidic strength and amount of each Lewis acid in these IL analogues, which can guide corresponding acid-catalyzed reactions.

For traditional ILs, the spectral measurement methods of the acidity are mainly UV-vis, NMR and IR spectroscopies. The UV-vis spectroscopy method determines semi-quantitatively the acidic strength of total Bronsted acid in ILs according to the Hammett function,¹⁰⁻¹² but it could not be applied in the analysis of Lewis acid in ILs, such as [Al₂Cl₇]⁻ in chloroaluminate ILs. The Lewis acidic strength can be quantified by the Gutmann acceptor number, which is directly proportional to the ³¹P NMR chemical shift of triethylphosphineoxide (TEPO) dissolved in ILs.¹³⁻¹⁴ The ³¹P NMR method can distinguish effectively the acidic strength of each Lewis acid in ILs with multiple Lewis acids, but it could not measure the acidic amount of each Lewis acid.¹⁵⁻¹⁷ The traditional KBr tableting IR uses nitrogen-containing compounds as molecular probes, such as pyridine and ethanenitrile. The change in the IR frequencies of the molecular probes is correlated to the acidic strength of the acid species in ILs. The tableting IR method can distinguish evidently the Bronsted and Lewis acid according to the wave-number of the characteristic peaks.¹⁵⁻¹⁷ For example, two peak at 1450 cm⁻¹ and 1540 cm⁻¹ were the indication of pyridine coordinated to Lewis and Bronsted acid, respectively.¹⁸ But this method neither distinguishes easily the acidic strength of each Lewis acid in ILs with multiple Lewis acids because of the overlap of characteristic peaks, nor can it measure the acidic amount of each Lewis acid. In addition, infrared studies of ammonia adsorption and microcalorimetry were also used by Dupont Company to investigate the acidity of zeolite.¹⁹

In this communication, we first establish a combinatorial method to determine the acidity of amide–AlCl₃ based IL analogues with multiple Lewis acids by combining in situ IR titration with NMR analysis. This method not only distinguished effectively the acidic strength of each Lewis acid in amide–AlCl₃ based IL analogues, but also measured the acidic amount of each Lewis acid.

Firstly, ³¹P NMR was used to identify the acidic strength of each Lewis acid in amide–AlCl₃ based IL analogues, as shown in Fig. 1. A single peak at 83.48 ppm was observed in the ³¹P NMR spectra of molecular probe (TEPO) dissolved in neat Et₄NHCl–AlCl₃ IL (molar ratio of Et₄NHCl to AlCl₃ was 0.65), which was assigned to the coordination of TEPO to Lewis acid. This result indicated that neat Et₄NHCl–AlCl₃ IL only contained single Lewis acid, namely [Al₂Cl₇]⁻. However, two peaks at 83.48 and 84.92 ppm were observed in neat NMA–AlCl₃ IL analogue (molar ratio of N-methylacetamide to AlCl₃ was 0.65, marked as 0.65NMA–1.0AlCl₃) with the addition of TEPO. This phenomenon indicated that another Lewis acid in addition to [Al₂Cl₇]⁻ existed in 0.65NMA–1.0AlCl₃. The peak at 84.92 ppm was
assigned to the cationic Al species because the molecule Al species was neutral. Meanwhile, the acidic strength of cationic Al species located in low field was stronger than that of [Al₂Cl₇]⁻.

Subsequently, in situ IR titration method was used to measure the acidic mount of two Lewis acids in neat 0.65NMA–1.0AlCl₃. The principle of this method is based on the online monitoring of the variation in the characteristic peaks formed by the coordination of indicator (nitrobenzene) with 0.65NMA–1.0AlCl₃. A quantitative measurement of the acidic amount of 0.65NMA–1.0AlCl₃ was made based on the typical procedure.

0.65NMA–1.0AlCl₃ (10 g) was placed into a 25 mL two-necked flask equipped with a stirrer. The silicon probe of the in situ IR apparatus was inserted into the 0.65NMA–1.0AlCl₃, and then the data on the IR spectra were collected. Next, nitrobenzene (0.25 g) was added dropwise to the flask and IR spectra were collected continuously until the absorbance of the characteristic peaks remained constant, meanwhile, the peaks of nitrobenzene itself were observed. The aforementioned steps were repeated until the absorbance of the characteristic peaks did not change with the addition of nitrobenzene. This point was marked as the terminal point of titration, the total mass of nitrobenzene added into 0.65NMA–1.0AlCl₃ was collected.

As a premise of the in situ IR titration method, the characteristic peak formed by the coordination of nitrobenzene with 0.65NMA–1.0AlCl₃ and the peak of nitrobenzene itself needed to be marked. Fig. 2 shows the IR spectra of neat nitrobenzene, neat 0.65NMA–1.0AlCl₃, and the mixture of 0.65NMA–1.0AlCl₃ with nitrobenzene. Two peaks at 1520 and 1346 cm⁻¹ were observed in neat nitrobenzene, which were assigned to the νas(O–N–O) and νs(O–N–O) stretching vibration of −NO₂ group, respectively. A new peak at 1260 cm⁻¹ was observed in the mixture of 0.65NMA–1.0AlCl₃ with nitrobenzene, which should be assigned to the coordination of nitrobenzene with Lewis acids. Meanwhile, the νas(O–N–O) stretching vibration at 1520 cm⁻¹ shifted to higher wavenumber 1537 cm⁻¹. The νs(O–N–O) stretching vibration at 1346 cm⁻¹ appeared only in the case that excess nitrobenzene were added into 0.65NMA–1.0AlCl₃. Therefore, the peaks at 1260 and 1346 cm⁻¹ were chosen as the characteristic peaks to observe in the following in situ IR titration method.

Fig. 2 IR spectra of (a) pure nitrobenzene; (b) neat 0.65NMA–1.0AlCl₃ based IL analogue; (c) nitrobenzene + 0.65NMA–1.0AlCl₃ based IL analogue (1 : 10 by mass ratio); (d) nitrobenzene + 0.65NMA–1.0AlCl₃ based IL analogue (1 : 4 by mass ratio).

Fig. 3 Trend of the characteristic peaks at 1260 cm⁻¹ and 1346 cm⁻¹ for the addition of nitrobenzene into 0.65NMA–1.0AlCl₃ based IL analogue.

Fig. 4 Surface plot in the 1390–1185 cm⁻¹ range for the 0.65NMA–1.0AlCl₃ based IL analogue with the addition of nitrobenzene.
Lewis acidic amount of 0.65NMA–1.0AlCl₃ was continuously consumed by nitrobenzene. When the Lewis acidic amount of 0.65NMA–1.0AlCl₃ was used up, the absorbance of the peak at 1346 cm⁻¹ had a significantly increase with the addition of nitrobenzene. The total mass of nitrobenzene from start to terminal point was recorded, and “the molar consumption of nitrobenzene per 1000 g IL analogue” was defined as “activity index” to evaluate the acidic amount of 0.65NMA–1.0AlCl₃.²⁶,²⁷

The Lewis acidic amount of several amide–AlCl₃ based IL analogues with different amide structures and amide/AlCl₃ molar ratios were measured by in situ IR titration method, as shown in Fig. 5. The amide structure affected the Lewis acidic amount of amide–AlCl₃ based IL analogues, for example, the Lewis acidic amount of amide–AlCl₃ based IL analogues (NMA–AlCl₃ and DMA–AlCl₃) with bidentate coordination was higher than that of amide–AlCl₃ based IL analogues (AA–AlCl₃ and Ur–AlCl₃) with monodentate coordination under the same amide/AlCl₃ molar ratio.²⁹ This phenomenon was attributed to the fact that the bidentate coordination was more favorable to the asymmetric splitting of AlCl₃ than the monodentate coordination with the same amide/AlCl₃ molar ratio, resulting in the more active Lewis species (anionic Al species and cationic Al species). On the other hand, the amide/AlCl₃ molar ratio also affected the Lewis acidic amount of amide–AlCl₃ based IL analogues. The Lewis acidic amount of amide–AlCl₃ based IL analogues increased with the decreasing amide/AlCl₃ molar ratio. For amide–AlCl₃ based IL analogues, the balance between neutral molecular Al species and ionic Al species was readily broken with the change of amide/AlCl₃ molar ratio. The asymmetric splitting degree of AlCl₃ increased and the molecular species transformed into ionic species as the amide/AlCl₃ molar ratio decreased, so the Lewis acidic amount of amide–AlCl₃ based IL analogue also increased.

The total Lewis acidic amount of amide–AlCl₃ based IL analogues could be measured by in situ IR titration method, but the acidic amount of anionic Al species and cationic Al species needed to be further determined.²⁷ Al NMR is a good tool to distinguish these Al species, and the peaks at 102.75, 89.30 and 77.05 ppm should be assigned to the anionic Al species ([Al₂Cl₇]⁻ and [AlCl₄]⁻), molecular Al species [AlCl₂Lₙ]⁺, and cationic Al species [AlCl₃Lₙ]⁺, respectively.²⁸ The integral area ratio of anionic Al species ([Al₂Cl₇]⁻, [AlCl₄]⁻) to cationic Al species ([AlCl₃Lₙ]⁺) was obtained by the normalization method of the peak areas, as shown in Fig. 6. The integral area

represented the number of Al nucleus (note: [AlCl2L]− had two Al
nuclei). Therefore, the integral area ratio of anionic Al species to
cationic Al species represented the molar ratio of 2 × [AlCl2L]− +
[AlCl4]− to [AlCl2L]−. The molar of [Al2Cl7]− + [AlCl4]− was equal
to that of [AlCl2L]− according to the conservation law of charge,
so the molar ratio of [AlCl2L]− to [AlCl2L]− could be calculated.
Taking NMA–AlCl3 based IL analogue with different NMA/AlCl3
molar ratios as an example, the acidic amount of two Lewis
acids ([AlCl2L]− and [AlCl2L]−) in NMA–AlCl3 based IL analogue
was calculated from the results of both in situ IR titration and
27Al NMR analysis, as listed in Table 1.

Conclusions

An efficient method to determine the acidic strength and acidic
amount of each Lewis acid in amide–AlCl3 based IL analogue
was proposed in this study. The 31P NMR using triethylphos-
phineoxide as a molecular probe showed that two active Lewis
acids ([AlCl2L]−, [AlCl2L]−) existed in amide–AlCl3 based IL
analogues, and the acidic strength of [AlCl2L]− was stronger
than that of [AlCl2L]−. The principle of the in situ IR titration
method was described in detail, and the total Lewis acidic
amount of these IL analogues was measured with nitrobenzene
as indicator. The results indicated that the total Lewis acidic
amount of amide–AlCl3 based IL analogues was related with
both the amide structure and the amide/AlCl3 molar ratio. The
amide–AlCl3 based IL analogues with bidentate coordination
structure and low amide/AlCl3 molar ratio had a high Lewis
acidic amount. The Lewis acidic amount of each Lewis acid
was calculated further by combining 27Al NMR analysis with in situ
IR titration.

Experiments

The general route for the synthesis of 0.65amide–1.0AlCl3 IL
analogue was as follows: anhydrous AlCl3 (0.2 mol) was placed
in 250 mL two-necked flask; then, amide (0.13 mol; N-methyl-
acetamide, NMA; N,N-dimethylacetamide, DMA; acetamide, AA;
urea, Ur) was added slowly while stirring for 30 min. The
mixture was then heated to 80 °C and maintained at that
temperature until all solids “dissolved” (approximately 4 h).34
IR spectra over the 4000 cm−1 to 650 cm−1 frequency range
were obtained at room temperature and at 8 cm−1 resolution
using an in situ IR spectrometer (Mettler-Toledo) equipped with
an attenuated total reflectance based silicon probe and a liquid
nitrogen-cooled mercury-cadmium-tellurium (MCT) detector.
IL analogue (10 g) was placed into a 25 mL two-necked flask
equipped with a stirring bar at room temperature. The silicon
probe was then inserted into the IL analogue, after which date
on the IR spectra were collected. Next, the indicator (0.05 g) was
added dropwise to the flask and IR spectra were collected continuously until the characteristic peaks remained constant.
The aforementioned steps were repeated. During the measurement,
the optical path of the spectrometer was continuously purged with dry N2 at a flow rate of 2 mL min−1 to eliminate moisture and CO2. 27Al and 31P NMR spectra were obtained using a Bruker Avance spectrometer.

The samples were placed into a 10 mm standard tube by inserting a well-centered capillary. Thereafter, the NMR tube was capped and sealed with paraffilm. The aqueous solutions of
Al(NO3)3 (1.0 mol L−1) and H3PO4 (85 wt%) in the capillary was
used as an external reference for the 27Al NMR and 31P NMR
chemical shift, respectively. Peak intensities and areas were
carefully measured using the Brucker-NMR software package.
